Vi comunico gli ultimi risultati che ho raggiunto dopo molte intense ricerche per la miglior soluzione per la galena FM. La J antenna andava egregiamente, ma sopportava solo un collegamento brevissimo. Quando mi sono deciso di appendere verticalmente un dipolo di piattina, invece del classico posizionamento di detto, ho scoperto un mondo nuovo. Funziona egregiamente anche con una discesa, in piattina, di 6,5 metri. Solo in quel modo sono riuscito ad ascoltare costantemente e confortevolmente anche senza amplificazione. Ma non mi sono fermato lì: vista la forte corrente che si ricava da un diodo collegato al dipolo (oltre 50 microampere) ne ho usato uno per alimentare un EPAD. Ciò vale per l’FM ed anche per il Kit che ho fatto per la SANDIT.

con un buon segnale
funziona senza amplificatore

piattina da 300 ohm cortocircuitata sopra e sotto (144 cm per 100 MHz) appesa verticalmente

Tenendo staccata la cuffia, col condensatore da 0,1 F si raddoppia la V di aliment.

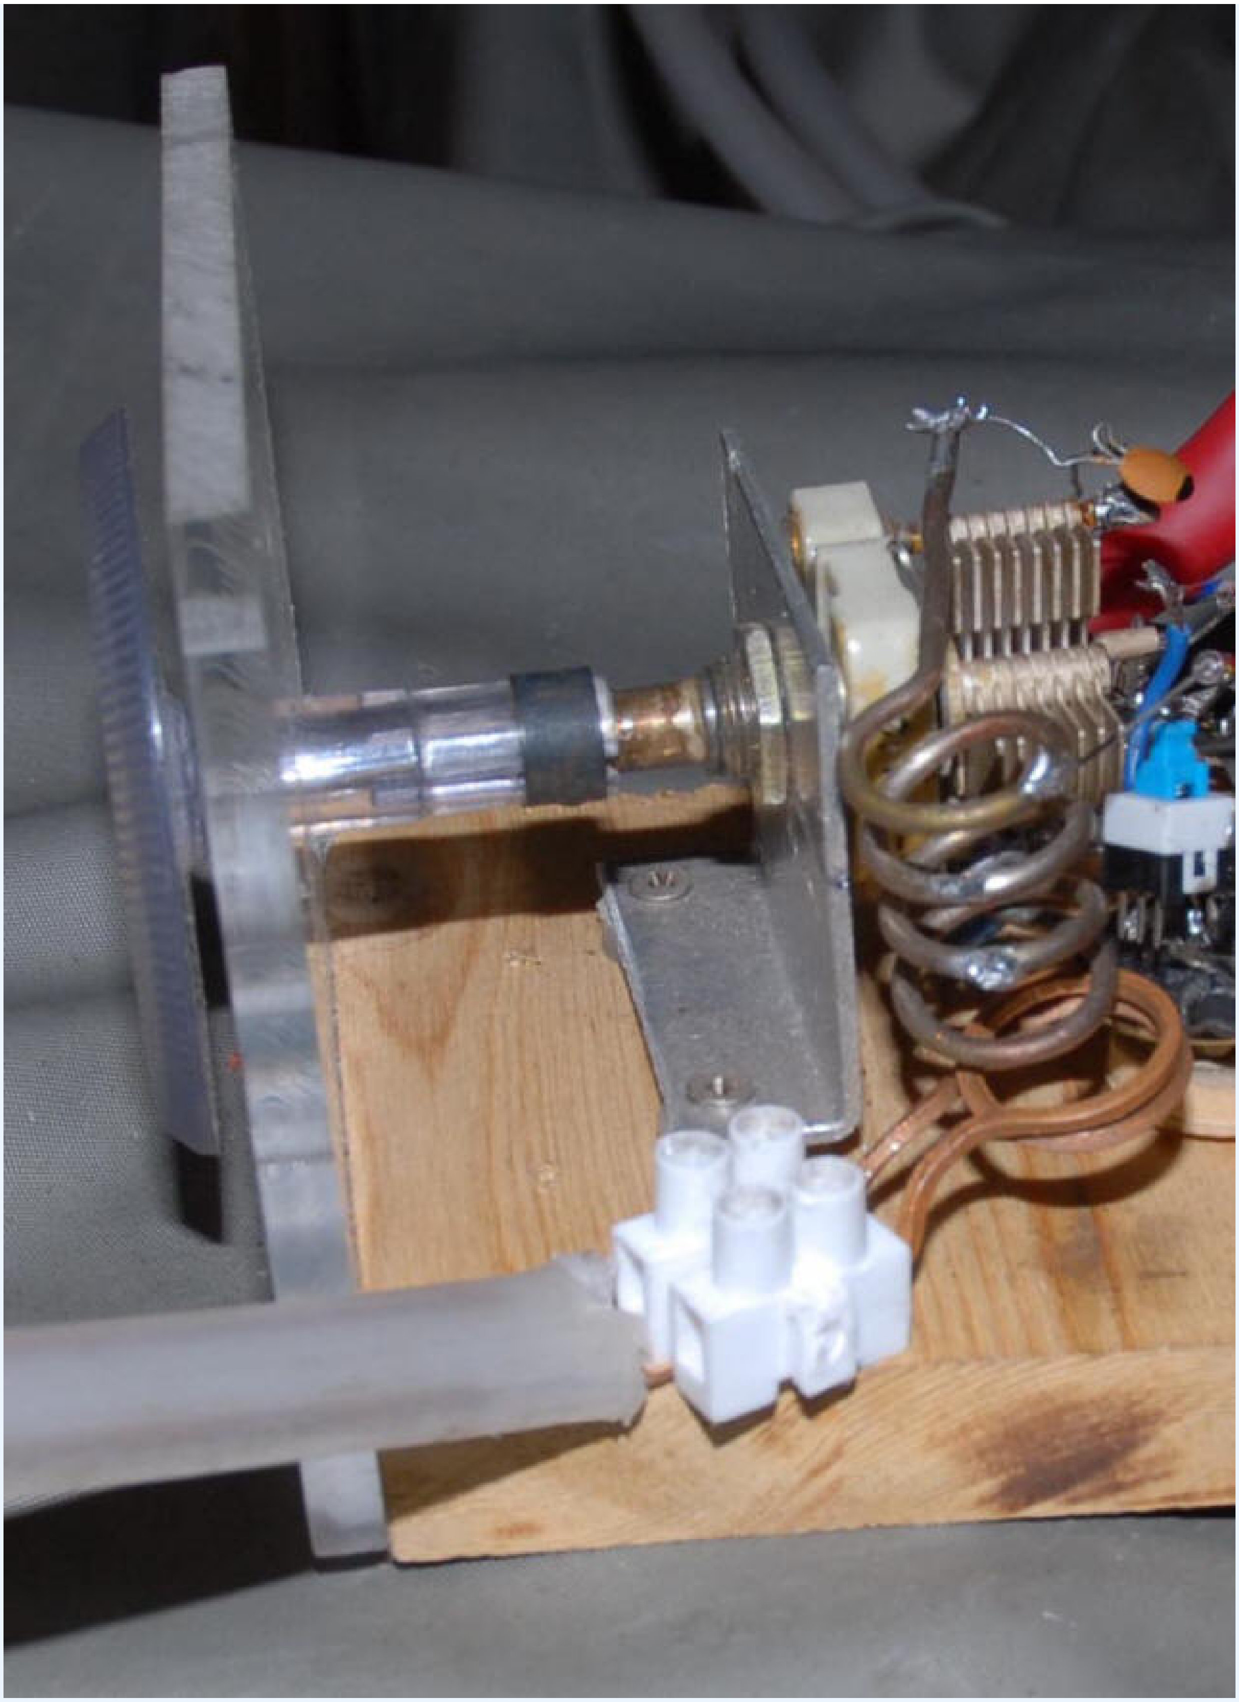
anche a distanza tenendo staccata la cuffia

GALENA PER FM AD ALIMENTAZIONE RUBATA

L'EPAD si può trovare presso la MOUSER USA, Monaco, Milano

La calata può essere di piattina oppure il diodo subito al dipolo e poi due normali conduttori

la piattina è lunga 0,96 lambda ovvero 144 cm per 100 MHz



La realizzazione con la semplice bobina illustrata mi ha dato intensità maggiore che con la cavità, anche se un poco più di rumore. Una realizzazione fatta usando per bobina un anello di tubo di ottone da 6 mm e 11 cm di diametro, che teoricamente ha un Q 4 volte maggiore di quella classica, mi ha deluso. Dunque avanti con la semplice bobina raccomandandomi di osservare attentamente il disegno allegato, seguirlo a lettera e non arrendersi quando alle prime prove non funziona:capita sempre così.

Radio a galena FM

per la “banda commerciale” 88 – 108 MHz

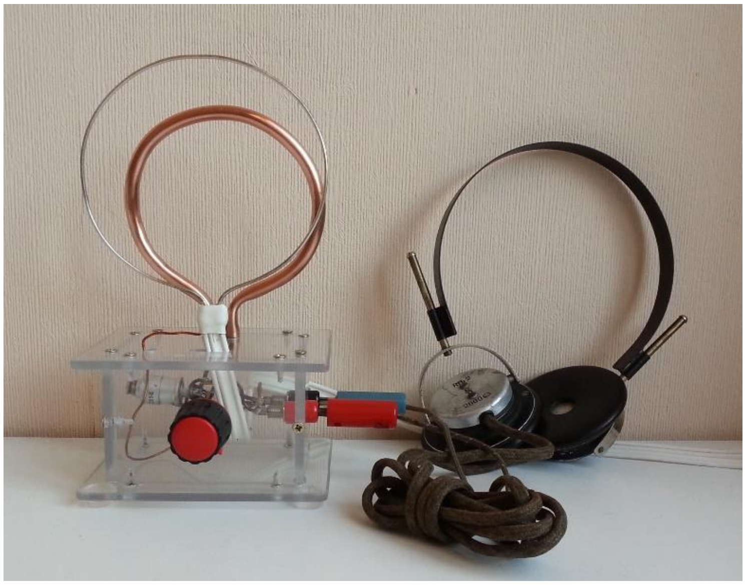


Figura 1: Radio a galena a montaggio ultimato.

Sono passati già otto anni da quando decisi di sperimentare con il primo ricevitore a galena. Lessi come costruirne uno proprio da questo sito (Realizza il tuo Primo Ricevitore a cristallo) e decisi di montarlo pensando di continuo che non avrebbe mai potuto funzionare veramente. La sorpresa nel “sentire qualcosa” da un vecchio auricolare telefonico è stata grande, e da allora la Vecchia Signora ha rapito la mia passione per l’elettronica, dirottandola verso la radiotecnica. Nonostante questa galena fosse pensata per ricevere segnali ad onde medie (come tutte le prime galene che si rispettino) è interessante notare che, già allora, quell’unica stazione che riuscivo a ricevere ho scoperto poi appartenere alla gamma delle onde corte… perché non è da pochi anni che le onde medie sono in crisi!
Stazioni abbastanza potenti per permettere un ascolto soddisfacente in cuffia da qualsiasi punto del Pese sono ormai quasi esclusivamente disponibili in onde corte, gamma che di sera offre segnali fortissimi provenienti da posti anche al di là del globo. Ma la radio a cristallo era pensata per permettere l’ascolto “dell’emittente locale”, e non di segnali provenienti da chissà dove, ed in chissà quale lingua! Sono cambiati i tempi, dunque… cambiamo anche la radio a glena, no? Eppure oggi le moderne tecnologie ed il più basso costo dei materiali permettono di realizzare ricevitori a cristallo di grandi prestazioni, proprio quando, paradosso, il tempo della radio a galena è da considerarsi ormai concluso.
L’unico territorio abbastanza inesplorato è quello della gamma broadcasting F.M., e ciò ha spinto gli appassionati amministratori e lettori di questo sito a sperimentare con le VHF, come è stato possibile notare dai progetti di radio a cristallo per FM che hanno fatto capolino da qualche anno ad oggi. Se si vuole sperimentare, d’altro canto, bisogna farlo subito giacché si sente parlare sempre di più di D.A.B. e di digitalizzazione…
È possibile ascoltare una radio a galena in FM solo se si abita nelle immediate vicinanze di un ripetitore; circa 10km di aperta campagna e di costa marina (ho provato) sono troppi per un ricevitore a cristallo.

Il caso ha voluto che andassi ad abitare in una città dove ci sono dei ripetitori, e questo mi è bastato per decidermi a sperimentare, rispondendo all'appello lanciato su questo sito qualche anno fa.
Questo articolo, già comparso nei numeri di giugno e di luglio-agosto della rivista Radiokit Elettronica, nasce come proposta di realizzazione del circuito presentato dal lettore Carlo Bramanti su questo sito (Galena per FM). Ad ogni modo il progetto da me proposto differisce alquanto dall'originale per la cruciale scelta del diodo rivelatore, del quale presento un piccolo "lavoro di ricerca", e per la presenza di un nuovo componente.

1. Schema elettrico

Il circuito elettrico della galena FM, riportato in Figura 2, risponde all'esigenza di essenzialità tipica di ogni ricevitore a cristallo. Lo schema elettrico deve essere semplice, soprattutto se si vogliono ricevere deboli segnali, per di più nella banda delle onde ultracorte.

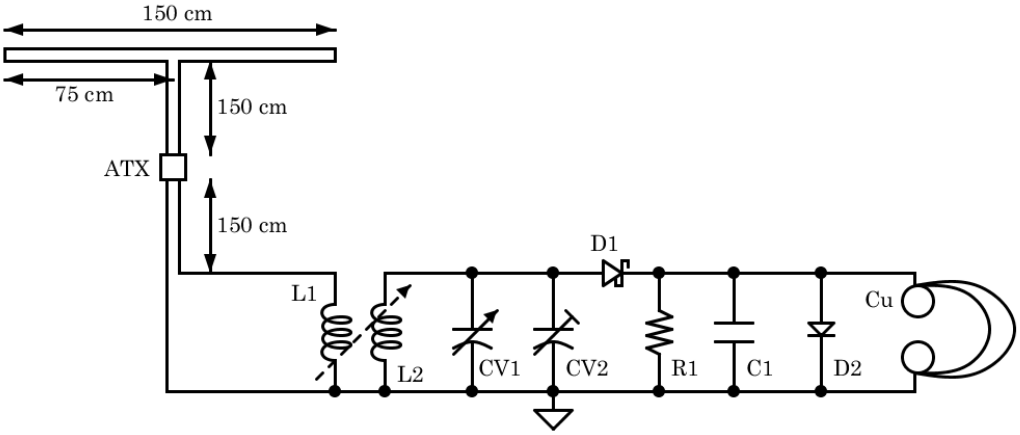

Figura 2: Schema elettrico della radio a galena FM.

I componenti adoperati sono:

- L1 = vedi testo (sezione Bobine L1 e L2);
- L2 = $0.137\mu H$, vedi Figura 7;
- CV1 = Johnson 160-211-1 $(2.7 - 10.8)pF$ per sezione;
- CV2 = trimmer tubolare da $(5 \div 15)pF$;
- D1 = diodo Schottky Skyworks modello SMS7630-001;
- D2 = diodo di segnale 1N4148;
- R1 = $47k\Omega$, $1/4$W;
- C1 = $100pF$ ceramico a disco;
- Cu = cuffie ad alta impedenza ($2k\Omega$ o superiore);
- ATX = connettore ATX femmina e header pin;
- Due connettori banana femmina.

Il segnale ricevuto dall'antenna è inviato alla bobina L1 che, insieme all'induttanza L2, forma un trasformatore RF in aria. L'induttore L1 è quindi il classico "primario aperiodico" il cui accoppiamento alla bobina di sintonia L2 è variabile a piacere. Il circuito accordato per la sintonizzazione delle stazioni è completato dall'ancor più classico condensatore variabile CV1 e dal correttore CV2, indispensabile

per la taratura del ricevitore. Seguono poi il diodo rivelatore D1 ed il filtro di deenfasi, costituito dal resistore R1 e dal condensatore C1.
Un componente piuttosto insolito, presente nella mia radio, è il diodo D2, in parallelo all'uscita; del tutto assente nelle classiche galene, questo diodo serve per proteggere il rivelatore, ed il motivo della sua presenza verrà spiegato più avanti.
Un paio di cuffie ad alta impedenza Cu completano il tutto, e possono essere sostituite da un qualsiasi amplificatore (va bene anche l'ingresso del microfono di un PC).

2. Realizzazione

Come in tutti i ricevitori a cristallo la realizzazione è sempre un passo importante; ottime saldature e collegamenti cortissimi sono la chiave per ottenere una radio a galena funzionante. Di seguito vi riporto nel dettaglio le varie fasi del montaggio arricchite di consigli empirici e note pratiche in parte sperimentate per la prima volta con questo ricevitore.

2.1. Antenna

Per questa radio le antenne possibili sono tante, ma ho condiviso la scelta del dipolo ripiegato già proposta da Carlo Bramanti per diversi motivi: Perché ha una resistenza di irradiazione di circa 300Ω, maggiore rispetto a quella del classico dipolo (75Ω), quindi tensioni di segnale più alte ai capi dell'antenna; perché è piuttosto compatta (basta con le antenne chilometriche ed ingombranti!) ma, soprattutto, perché ho trovato un modo facile e veloce per realizzarla. Sono riuscito a reperire una piattina per i vecchi impianti elettrici (una rimanenza di una ferramenta) che comprendeva pure il conduttore di messa a terra. Dopo averlo eliminato ho ritagliato la piattina in tre parti, di lunghezza indicata in Figura 2, per realizzare così un dipolo ripiegato ed un cavo di discesa. L'antenna a montaggio ultimato si presenta come in Figura 3. In pratica ho spelato i due conduttori alle estremità di uno dei pezzi da $150cm$ per poi saldarli tra loro.

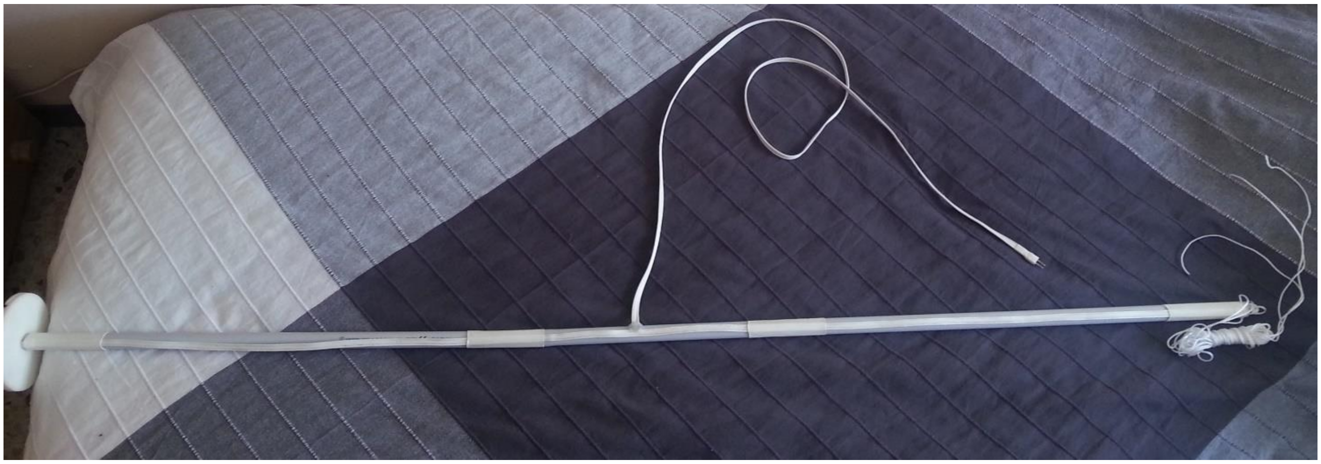

Figura 3: Dipolo ripiegato a montaggio ultimato.

Ho poi tagliato al centro uno dei due fili per realizzare la presa centrale per "il cavo di discesa", quello che termina con il connettore header pin (Figura 3). Il particolare della presa è visibile in Figura 4.
Chi non riuscisse a reperire una piattina (ormai non più in commercio) può sempre acquistare un dipolo

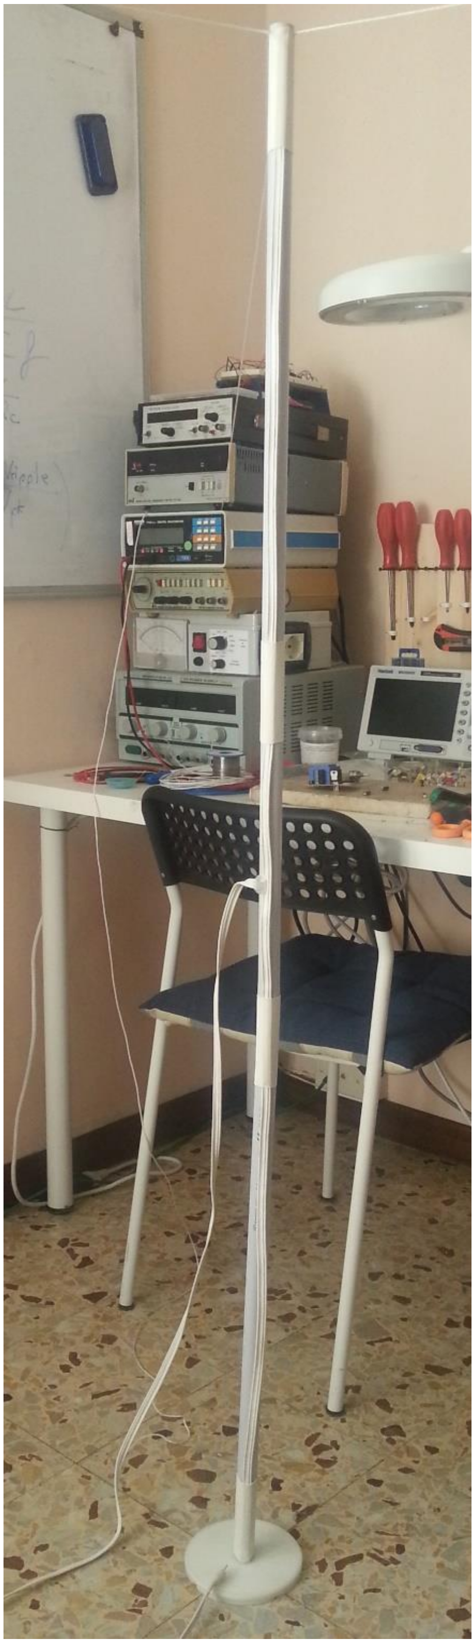

Figura 6: Esempio di impiego del dipolo ripiegato.

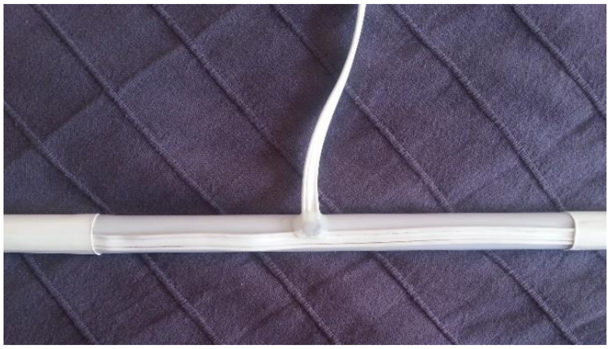

Figura 4: Particolare della presa per il cavo di discesa.

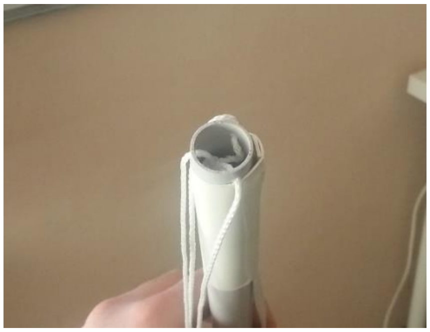

Figura 5: Particolare dei cordini fissati alla canalina.

ripiegato già pronto all'uso, di quelli venduti per i sintonizzatori degli impianti stereo domestici. Di solito anche queste antenne sono realizzate con una piattina di colore rossiccio/rosa trasparente.

Per poter mantenere l'antenna sempre "in piedi" ho pensato di fissarla su una canalina da $2cm$ di diametro, e lunga $152cm$ (poco più del dipolo, insomma). Per il fissaggio (peccato che non si possano usare viti metalliche…) ho adoperato degli spezzoni di tubo di gomma termorestringibile bianchi, lunghi circa $10cm$, e disposti a distanza quasi regolare, come visibile in Figura 3.

La presa centrale (Figura 4) è stata invece fissata con della colla termica trasparente. Sempre dalla Figura 3 si può notare anche una matassina di cordino bianco; è una corda da $1.5mm$ di diametro, di polipropilene (abbastanza anti ingarbugliamento) ritagliata in tre pezzi lunghi ciascuno due volte la lunghezza del dipolo. Economica, questa corda mi ha permesso di fissare l'antenna in qualsiasi punto di una stanza, realizzando dei rapidissimi tiranti. Basta fare un paio di nodi ed il dipolo ripiegato si mantiene in piedi, come si può vedere dalla foto di Figura 6. Questa soluzione, tanto semplice quanto funzionale, permette anche di appendere l'antenna, per fissarla in punti più in alto, lontani dalle pareti e dal pavimento. Ai non addetti ai lavori preciso che è indispensabile che l'antenna sia posizionata verticalmente, come di Figura 6, perché verticale è la polarizzazione dei segnali irradiati dai ripetitori FM che si vogliono ricevere; posizionando l'antenna orizzontalmente (ho anche provato!) non si riceve nessuna stazione. Per assicurare i cordini alla canalina ho praticato tre fori, come in Figura 5, ed ho unito le tre corde in un unico grosso nodo, riscaldato poi alla fiamma. Ho stampato in 3D anche una piccola base (il disco bianco di Figura 6), che contribuisce alla stabilità del dipolo, anche se non è strettamente necessaria. Chi non ha una stampante 3D può sostituire la base magari con un piatto di plastica (di quelli rigidi) ed un tappo di sughero…

Il dipolo così realizzato è accordato circa al "centro banda". Ricordando infatti che in un dipolo ripiegato i nostri $150cm$ rappresentano metà della lunghezza d'onda del segnale che si vuole sintonizzare, la frequenza corrispondente è data dalla relazione:

$$f = \frac{c}{\lambda} = \frac{3 \cdot 10^8 m/s}{2 \cdot 1.5m} = \ 100MHz$$

$75cm$ rappresentano quindi un quarto della lunghezza d'onda relativa al segnale a $100MHz$.

Per trasportare facilmente l'antenna e la radiolina ho pensato di interrompere il cavo di discesa con un connettore header pin maschio, che andrà poi innestato ad un connettore ATX, di quelli usati negli alimentatori dei PC per portare i $12V$ alla scheda madre. Ho adoperato questo tipo di connettore perché, oltre che essere robusto, presenta una distanza tra i due conduttori che è simile a quella della piattina, e magari il disadattamento introdotto lungo la linea del cavo di discesa è ridotto al minimo (trascurando la discontinuità dell'isolante).

2.2. Bobine L1 e L2

La piattina del cavo di discesa termina direttamente con la bobina L1. Questa è stata realizzata con un filo di rame argentato da $1.6mm$, avvolta a formare una sola spira circolare di circa $9.5cm$ di diametro. A fine realizzazione la ho subito protetta con dello spray di vernice trasparente, che ha la funzione di preservare il prezioso metallo dall'ossidazione pur non coprendone il colore originale.

Questa bobina così fatta è molto bella a vedersi; l'attenzione per l'estetica è una delle linee guida che ho cercato di seguire per realizzare questa radio, ed è una diretta conseguenza del tipo di montaggio scelto: scatola in plexiglass per avere tutto il circuito in vista. In ogni caso la sua induttanza non è molto importante; le prove che ho fatto hanno confermato che l'importante è che il diametro della spira sia pari o superiore al diametro medio della bobina L2. Non è neanche necessario che la bobina L1 sia accordata con un condensatore in serie, perché ci ho provato e non ho ottenuto migliorie.

Ho realizzato poi la bobina L2 piegando in una sola spira circolare un tubo di rame da $7mm$ di diametro; tutte le sue dimensioni sono indicate nell'immagine di Figura 7.

Questa è una delle soluzioni possibili per avere un'induttanza con un alto fattore di merito (purtroppo ad oggi non ho un Qmetro funzionante, e quindi non ho potuto misurarlo). L'induttore ottenuto ha quindi delle ridotte capacità parassite (una sola spira) ed un ridotto effetto pelle, avendo a disposizione un'ampia superficie di conduttore. Il tubo che ho adoperato infatti è cavo, di quelli impiegati per gli impianti dei climatizzatori, e reperito ad un brico. Vi auguro di trovarne uno con un diametro inferiore al mio, perché già $7mm$ è il massimo possibile per realizzare un'induttanza da $0.137\mu H$.

Per diametri maggiori, infatti, il tubo diventa veramente difficile da lavorare. Lo è stato già il mio, che sono riuscito a sagomare aiutandomi con una piccola morsa, dopo averlo piegato gradualmente su supporti di diametro decrescente. Al fine di ridurre l'effetto pelle è indispensabile che il rame non sia minimamente ossidato. Teoricamente, se non si tocca il tubo con le mani (il sebo della nostra pelle poi a contatto con l'ossigeno ossida il metallo) quindi adoperando i guanti, e se si riesce a lavorarlo in poco tempo, per poi subito proteggerlo con della vernice, sarebbe possibile evitare che si ossidi. In realtà ciò è difficile a farsi; il tubo è già molto difficile da piegare afferrandolo con le mani nude, figuriamoci con i guanti! … ma con un po' di pasta abrasiva si può eliminare tutto l'ossido ripristinando la lucentezza tipica del rame. Ed è questa la soluzione che ho usato per rendere bella la mia realizzazione, spruzzando quattro mani di vernice trasparente acrilica sulla bobina, dopo averla lucidata.

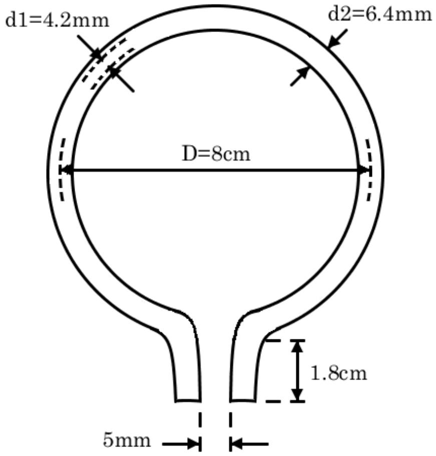

Figura 7: Dimensioni della bobina realizzata.

Per calcolare il valore dell'induttanza L2 ho faticato davvero tanto (con mia grande sorpresa!) a trovare la formula. Sono riuscito a trovarne una approssimata sul Radio Engineering Handbook (F. E. Terman) e, anche se non è di facile impiego, ve la riporto qualora doveste ottenere un'induttanza da $0.137\mu H$ con un tubo di diametro minore del mio (cosa che continuo ad augurarvi). Con riferimento alla Figura 7, l'induttanza di un tubo ripiegato a forma di Ω è:

$$L = 0.01595 \cdot D \cdot \left[2.303 \cdot \log_{10}\left(\frac{8 \cdot D}{d_2}\right) - 1.75 - \frac{d_1^2}{2 \cdot (d_2^2 - d_1^2)} + 2.303 \cdot \frac{d_1^4}{(d_2^2 - d_1^2)^2} \cdot \log_{10}\left(\frac{d_2}{d_1}\right)\right]$$

dove:

- L = induttanza in micro Henry;
- D = diametro medio della spira in pollici (come al solito!);
- d_1 = diametro interno in pollici;
- d_2 = diametro esterno, sempre in pollici.

Scusate per i pollici, ma se avessi incluso anche il fattore di conversione, la formula sarebbe diventata illeggibile. In ogni caso vi ricordo che, per passare dai pollici ai centimetri, basta dividere i centimetri per 2,54. Con un foglio Excel od una calcolatrice scientifica si può provare a variare il diametro D, fino ad ottenere il valore di induttanza voluto; il Terman consiglia comunque la possibilità di semplificare la formula per frequenze molto alte, come segue:

$$L = 0.01595 \cdot D \cdot \left[2.303 \cdot \log_{10}\left(\frac{8 \cdot D}{d_2}\right) - 2\right]$$

2.3. Condensatore variabile, rivelatore e filtro di deenfasi

Il condensatore variabile CV1 collegato in parallelo alla bobina L2 è del tipo ad aria con rotore a farfalla, ad alto fattore di merito, pensato per alte frequenze. È composto da due sezioni identiche, ma io ne ho usata una soltanto (avevo solo questo nel cassetto!). Considerando che il montaggio introduce una capacità parassita di almeno $10pF$ (è un valore molto ottimistico, lo so, ma con collegamenti cortissimi ci si può riuscire), e che il trimmer CV2 ha una capacità minima di $5pF$, è possibile sintonizzarsi sull'intera gamma FM con il variabile scelto. Il segnale radio così sintonizzato viene poi demodulato dal diodo D1 con la tecnica del classico "rivelatore a pendenza".

Il circuito RC-parallelo formato da C1 e R1 costituiscono, come già accennato, il filtro di deenfasi. Tale filtro deve essere del primo ordine, e con frequenza di taglio di $3.2kHz$ circa. Ho calcolato quindi i valori di R1 e C1 ipotizzando di collegare all'uscita del circuito un amplificatore ad alta impedenza (maggiore di $47k\Omega$, nel mio caso). A rigore avrei dovuto calcolare il condensatore C1 sulla base dell'impedenza di $4k\Omega$ offerta dalle mie cuffie, ma la qualità del segnale ascoltato non permette di apprezzare queste differenze. Ho provato infatti a collegare in parallelo alle cuffie un condensatore di valore idoneo, più alto, ma sono rimasto deluso nel non sentire alcuna differenza! Ho preferito allora lasciare valori bassi di C1, anche perché questo shunta a massa il segnale RF residuo, quindi è bene che sia ceramico, di piccola capacità. Il resistore R1, d'altronde, essendo collegato in parallelo all'uscita, tenderebbe a cortocircuitare il già debole segnale che si vuole ascoltare, quindi è bene che il suo valore sia più alto possibile.

2.4. Diodo di protezione

I'1N4148 serve da protezione per il delicato diodo rivelatore. Data la bassa tensione di soglia dell SMS 7630 – 001, dal datasheet si legge che la massima tensione inversa applicabile *Vr* è di circa $1V$. Peccato che le tensioni a vuoto indotte dalle cuffie, quando le si urtano un po' tra loro (o semplicemente le si appoggiano sul tavolo) sono di circa $6V_{pp}$, durata $1ms$ circa, e possono arrivare anche a $20V_{pp}$! Le cuffie infatti, come ogni trasduttore, possono funzionare "al contrario", fungendo da microfono, e generando segnali di valore elevato, data la loro alta impedenza. Per questo motivo, in parallelo all'uscita (quindi alle cuffie) ho inserito un "veloce" 1N4148, che tosa tutti i picchi maggiori di circa $0.6V$, impedendo quindi la rottura del rivelatore. Il lettore attento avrà certamente notato che il diodo "di protezione" potrebbe tosare anche il segnale radio che si vuole ascoltare; in realtà ciò non può mai accadere poiché, con le cuffie inserite, il segnale di uscita ha un valore massimo di picco di circa $250mV_{pk}$. Questa condizione sarebbe comunque da verificare, giacché la tensione del segnale di uscita dipende molto dalle cuffie adoperate. Il massimo valore di $250mV_{pk}$ è assicurato dato che, per ottenere questa misura, ho collegato alla radio direttamente l'uscita dell'oscillatore modulato, che quindi mi ha fornito i segnali più ampi possibili sintonizzabili con la galena. La presenza del diodo D2, in ogni caso, introduce una capacità trascurabile in parallelo al filtro (circa $5\ pF$), dunque la sua frequenza di taglio non viene alterata.

Un paio di connettori a banana completano il tutto, permettendomi di calzare le mie Siemens da $4k\Omega$ e godermi l'ascolto di qualche stazione (cuffie ad alta impedenza sono strettamente necessarie dati i debolissimi segnali in gioco). Ai meno esperti raccomando di collegare in parallelo all'uscita un'induttanza da $100mH$ o superiore, qualora decideste di optare per un paio di auricolari piezoelettrici (es. buzzer) al posto delle classiche cuffie ad alta impedenza, che magari non avete a disposizione. Tale induttanza servirebbe per cortocircuitare la tensione continua che altrimenti si accumulerebbe ai capi del condensatore C1, polarizzando il diodo e bloccandone l'azione rivelatrice, impedendovi quindi di sentire alcunché. Il resistore R1, comunque, dovrebbe già assolvere a questo compito, ma, a mio avviso, sarebbe opportuno verificare caso per caso.

2.5. Cablaggio

Per il cablaggio del circuito ho usato del filo di rame smaltato da $2mm$ di diametro per collegare la bobina L2 e lo statore del CV1, mentre per il diodo rivelatore è bastato un filo da $1{,}8mm$. Come è possibile notare dalla foto del montaggio (Figura 8) i collegamenti sono ordinati e corti, con fili che non sono mai piegati ad angolo retto, cosa da evitare assolutamente in alta frequenza.

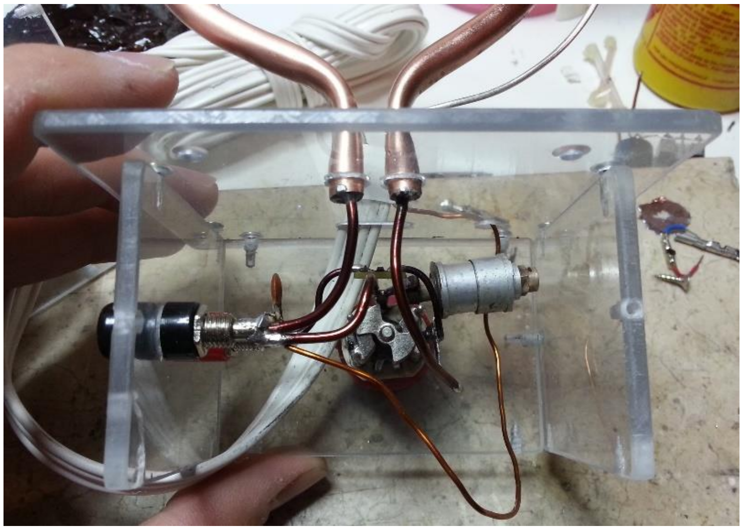

Figura 8: Vista posteriore del cablaggio

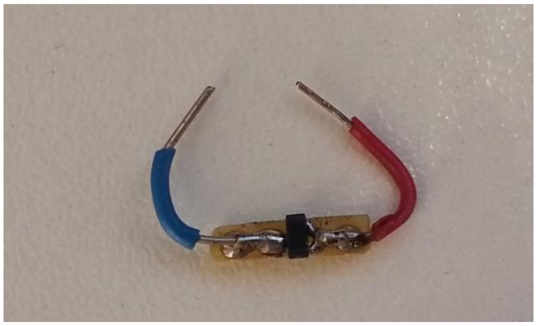

Figura 9: Particolare del diodo sulla basetta millefori.

Il filo di rame smaltato più chiaro e più sottile che si allunga verso il basso, visibile in Figura 8, serve per collegare un capo della bobina d'antenna con quello che è stato scelto come il riferimento del circuito. In questa maniera si può fare a meno della presa di terra per assicurare un percorso di ritorno per il segnale, ottenendo gli stessi risultati. Questo filo serve anche per mantenere la bobina d'antenna nella posizione scelta per realizzare l'accoppiamento voluto con la bobina di sintonia.

Il diodo rivelatore che ho impiegato nel mio circuito ha un contenitore tipo SOT-23, quindi pensato per il montaggio in SMD. In realtà il diodo non è troppo piccolo per essere saldato con una punta standard di un saldatore qualsiasi, quindi mi è bastato ritagliare una striscetta di una fila di basetta millefori, con quattro piazzole. Dalla Figura 9 si può vedere che il diodo occupa lo spazio tra una piazzola e la successiva; gli altri due reofori esterni sono stati usati per saldare i due fili che mi sono serviti per provarlo.
I collegamenti del diodo al resto del circuito sono visibili in Figura 10.

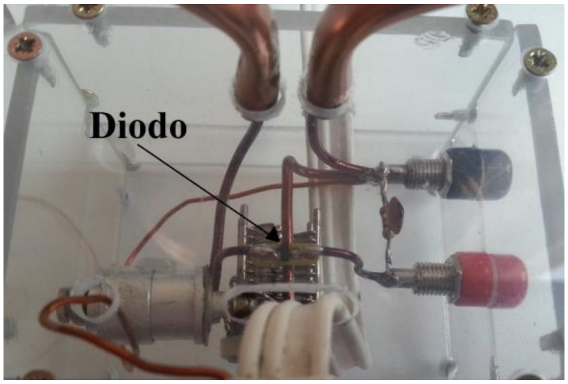

Figura 10: Cablaggio del diodo rivelatore.

A montaggio ultimato, nella sua scatola di plexiglass da $3.5mm$ di spessore, la radiolina appare come nelle immagini di Figura 11, Figura 12, Figura 13 e Figura 14.

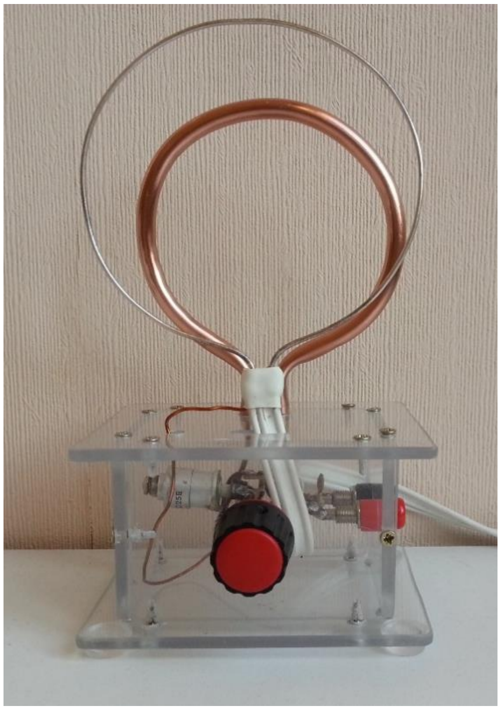

Figura 11: Vista frontale.

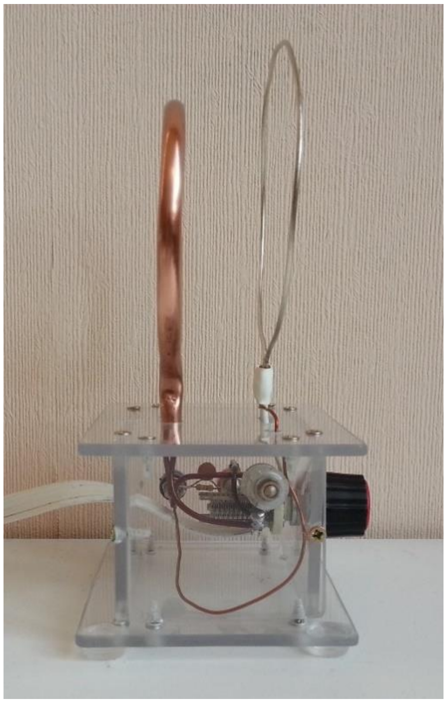

Figura 12: Vista laterale sinistra.

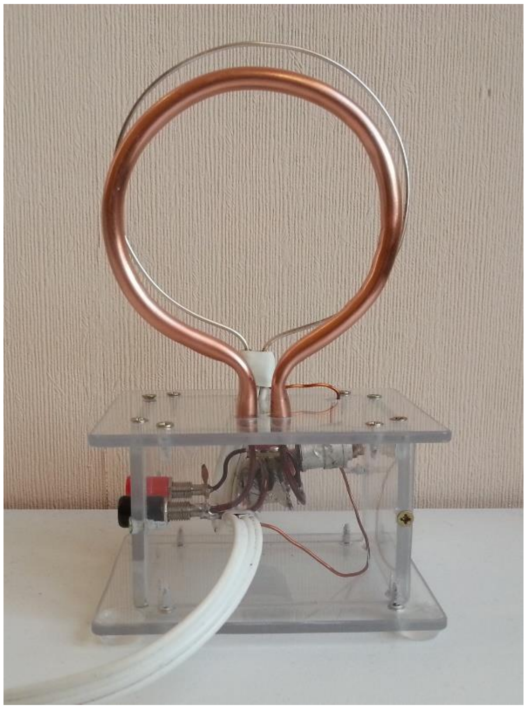

Figura 13: Vista posteriore.

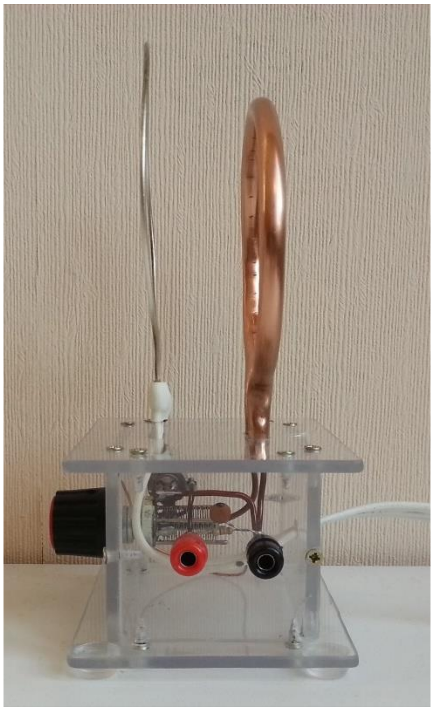

Figura 14: Vista laterale destra.

La realizzazione di un mobile con questo materiale è da sconsigliare per chi, come me, non ha un laboratorio attrezzato con apparecchi di precisione per il taglio e la foratura. Il plexiglass mette molto in risalto i minimi graffi, ed è piuttosto difficile da lavorare e "tagliare dritto". Tuttavia non ho rifatto la scatola avendo impiegato molto tempo per realizzarla. Per fissare i vari pannelli tra loro ho adoperato un metodo che mi ha permesso di ottenere un montaggio solido: ho forato il plexiglass con una punta da $2mm$, per poi inserirvi delle viti autofilettanti dal diametro poco superiore. Il risultato estetico ottenuto non è un granché (a parer mio), perché nei pannelli si vedono delle protuberanze biancastre al posto delle "viti affogare nel vetro", effetto che speravo di ottenere. In ogni caso il contenitore completamente trasparente ha il suo fascino, anche se costringe a posizionare i vari fili di collegamento in un certo modo, che possa essere insieme bello da vedere e fatto per ridurre al minimo le capacità parassite e la lunghezza dei collegamenti.
Con questo credo di avervi raccontato tutto… della complicata teoria dice che i segnali FM ricevuti sono molto deboli quindi, per realizzare una soddisfacente radio a galena su questa gamma bisogna avere l'antenna migliore (spero di averla!) le bobine con il più alto fattore di merito (le abbiamo) un buon condensatore variabile e delle cuffie ad alta impedenza (non credo ce ne siano da più di $4k\Omega$). Ma se il segnale è debole, ci vuole un ottimo diodo rivelatore, con bassissima tensione di soglia, e magari a basso rumore (e piccole capacità parassite). Ad una fiera dell'elettronica trovai degli strani diodi, venduti come "diodi tunnel". Avevano i terminali cortissimi, per essere innestati in degli appositi connettori, con un contenitore cilindrico plastico, marrone. Erano gli 1N82A; ne presi un po', convinto che un giorno li avrei usati per chissà quale strana applicazione. Dopo aver visionato il datasheet scoprii che erano in realtà dei diodi mixer adatti per le bande VHF/UHF. Avevo a disposizione anche i classici OA90, OA95, AA117, e 1N542. Dopo aver montato un primo prototipo di galena ho provato tutti questi diodi, scoprendo che la situazione era talmente tanto critica che solamente due degli esemplari di 1N82A permettevano un ascolto soddisfacente in cuffia. Nel tentativo di fare tutte le prove possibili per migliorare al massimo la mia radio, ho deciso di acquistare un po' di diodi RF, del tipo "mixer" o "zero-bias", a bassa tensione di soglia, e di cercare il migliore tra questi.

3. Alla ricerca del "diodo migliore"

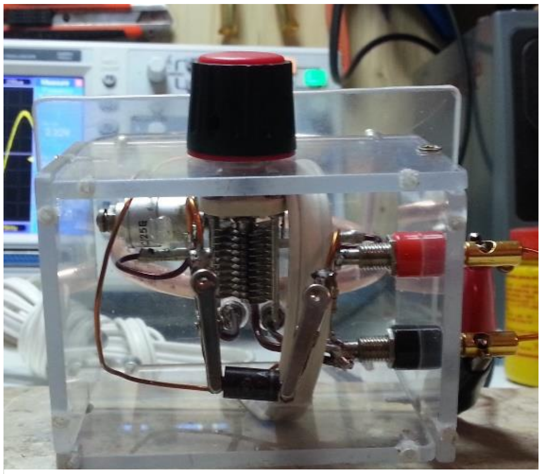

Figura 15:Particolare dei coccodrilli montati per provare i candidati diodi

Per riuscire in questa impresa ho pensato di non fare troppe cerimonie, testando magari il diodo in "circuiti equivalenti" a quelli della mia radio, ma di fare alcune misure collegando il diodo nello stesso circuito nel quale poi l'avrei usato: la mia radio, appunto. Per provare agevolmente tutti i rivelatori candidati ho saldato dei coccodrilli come in Figura 15. Dopo qualche prova preliminare con l'oscillatore modulato mi sono subito reso conto che la misura del segnale rivelato dopo il filtro di deenfasi era tutt'altro che banale, perché il segnale BF ai capi delle cuffie era molto distorto e rumoroso, oltre che "piccolo".
Dopo tante prove sono pervenuto all'allestimento del banco di misura illustrato in Figura 16 e Figura 17, e schematicamente rappresentato in Figura 18.

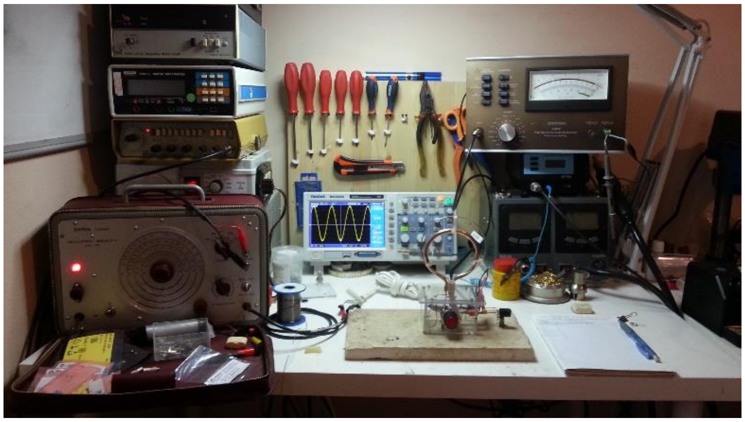

Figura 16: Banco di misura.

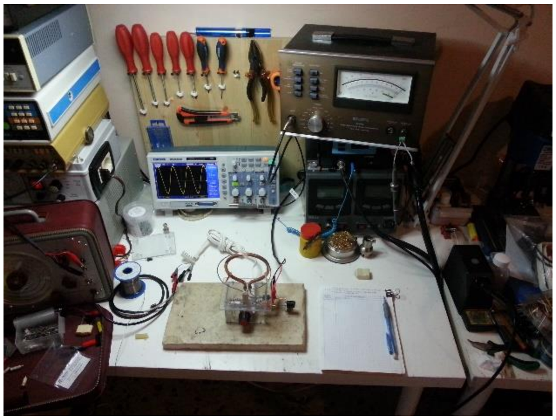

Figura 17: Vista superiore del banco di misura.

Le impostazioni degli strumenti, in parte già presenti in Figura 18, sono:

- **Generatore di funzioni**: segnale di uscita sinusoidale, ampiezza $400mVpp$ (con uso dell'attenuatore di 30 dB), frequenza $1kHz$, senza offset;
- **Oscillatore modulato**: ingresso per modulazione esterna selezionato, frequenza (misurata con l'oscilloscopio) di $88MHz$, attenuatore regolato per la massima ampiezza del segnale d'uscita;
- **Noisemeter**: amplificazione $1mV$ fondo scala, filtro CCIR inserito.

Figura 18: Schema del banco di misura messo a punto.

Gli accorgimenti che mi hanno permesso di ottenere un segnale rivelato pulito sullo schermo dell'oscilloscopio sono stati:

- La sistemazione dei cavi di collegamento lontano dalla galena.
- La scelta di un segnale di modulazione esterno perché quello generato internamente è distorto. L'ampiezza del segnale modulante è stata scelta la massima possibile per non avere sovramodulazione;

- La scelta di un segnale di $88MHz$ per l'oscillatore modulato perché il segnale dello strumento a quella frequenza è più ampio. In ogni caso non sarei mai riuscito a sintonizzarmi sull'estremo alto della gamma con le capacità parassite aggiunte dai coccodrilli di Figura 15;
- Il doppio filtraggio del segnale audio ottenuto sia con un circuito accordato alla frequenza di $1kHz$, collegato all'uscita della radio, sia con il filtro CCIR del noisemeter. La frequenza di $1kHz$ è stata scelta perché la curva CCIR non amplifica né attenua a questa frequenza. Ho prediletto poi questo filtro del noisemeter perché è quello che presenta il maggior filtraggio della banda audio.

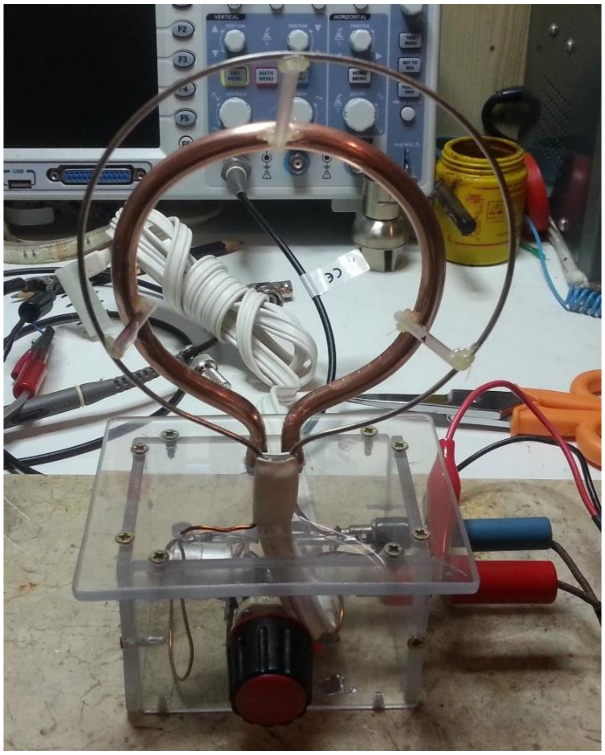

Figura 19: Vista frontale dell'accoppiamento fisso delle bobine.

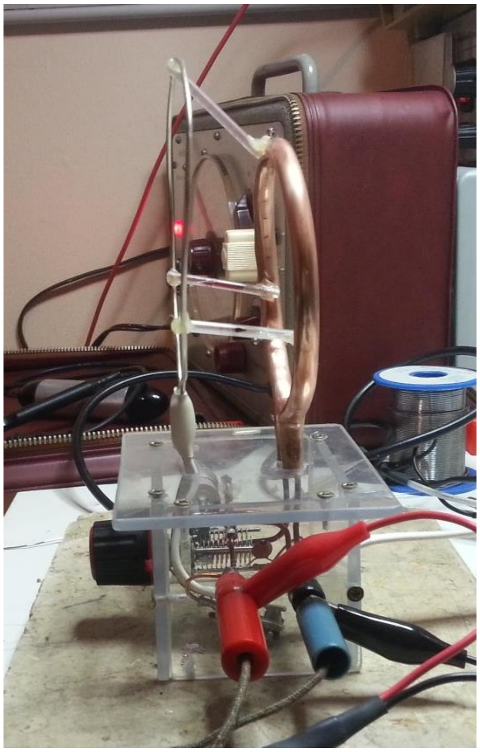

Figura 20: Vista laterale dell'accoppiamento fisso delle bobine.

Prima di eseguire le misurazioni ho atteso più di 20 minuti per permettere a tutti gli strumenti di "riscaldarsi".
Per ottenere delle misure coerenti tra un diodo e l'altro ho agito in questo modo:

- Per prima cosa ho fissato la bobina d'antenna alla bobina di sintonia per mezzo di tre spezzoni di tubetto di plastica (ex contenitore di inchiostro di penna Biro) incollati con colla termica, come indicato nelle foto di Figura 19 e Figura 20. In questa maniera l'accoppiamento tra L1 e L2 è stato sempre lo stesso per tutti i diodi;
- Ho inserito nel circuito dapprima il diodo 1N82A, che ho scelto come riferimento; mi sono accertato che il massimo segnale udito in cuffia durante l'operazione di sintonizzazione corrispondesse alla massima ampiezza del segnale sinusoidale misurato con l'oscilloscopio e con il noisemeter;
- Ho eliminato le cuffie perché tendevano a sporcare il segnale; dopo di che ho misurato tutti gli altri diodi;

- Ogni volta dopo aver inserito un nuovo diodo ho risintonizzato il ricevitore fino ad ottenere la massima deviazione dell'indice del noisemeter;
- Prima di misurare un nuovo diodo ho rimisurato l'1N82A per accertarmi di riottenere lo stesso valore letto dopo la prima misurazione;
- Ho eseguito le misure una di seguito all'altra, senza toccare i cavi di collegamento e restando seduto sempre nello stesso punto, onde evitare di variare gli accoppiamenti capacitivi tra il mio corpo e la radio ed i cavi;

Vi faccio presente che l'ingresso del noisemeter è ad alta impedenza ($1M\Omega$), quindi tutte le misure della Tabella 1 rappresentano i valori del segnale ad $1kHz$ misurato all'uscita della radio come se fosse "a vuoto". L'inserzione di un resistore da $4.7k\Omega$ per simulare il carico introdotto dalle cuffie ha avuto come effetto quello di ridurre troppo l'ampiezza del segnale in uscita, rendendolo ancora più rumoroso; quindi non l'ho usato. In ogni caso il filtro passivo ad $1kHz$, che idealmente non avrebbe dovuto "caricare" il circuito, ha ridotto di molto l'ampiezza del segnale rivelato, segno che, in realtà, un piccolo carico era comunque introdotto. Per questa ragione, onde visualizzare un bel segnale sullo schermo dell'oscilloscopio, ho adoperato l'uscita del noisemeter, che può essere usato come amplificatore calibrato. Un esempio del segnale demodulato si può intravedere sullo schermo dell'oscilloscopio nelle foto di Figura 16 e Figura 17. Ho adoperato anche l'oscilloscopio perché il Radford è un voltmetro a vero valore efficace, e avrebbe potuto fornirmi un massimo di tensione laddove in realtà l'ampiezza picco-picco del segnale rivelato non era massima. Con l'uso del noisemeter e dell'oscilloscopio ho potuto controllare volta per volta che il massimo segnale rivelato (Vpp) coincidesse con la massima deviazione dell'indice dello strumento.

Ad essere rigoroso avrei dovuto adattare l'impedenza di uscita dell'oscillatore modulato (50Ω) all'impedenza della piattina, che si aggira intorno a 300Ω. Ho deciso di non farlo perché l'adattatore d'impedenza fornito insieme all'oscillatore modulato, essendo passivo, riduceva di molto l'ampiezza del segnale generato. Il ricevitore ha comunque funzionato bene anche senza adattatori, segno che il disadattamento del circuito era trascurabile.

Nella Tabella 1 ci sono tre colonne, ed ogni colonna si riferisce alla misura di un esemplare del diodo indicato nella corrispondente riga. Questo perché, laddove il portafogli me lo ha consentito (alcuni di questi diodi sono piuttosto costosi) ho acquistato tre esemplari dello stesso diodo, sulla scorta del fatto che dei sei diodi 1N82A che avevo, soltanto tre hanno funzionato a dovere, mentre soltanto due erano utilizzabili come rivelatori. Ho rieseguito le misure per più di una volta, ed i valori riportati sono da intendersi con una "precisione" (accuratezza) di $0.05mV_{eff}$ in più o in meno.

Le misure riportate mi sono servite quindi per vedere quali tra i diodi provati mi fornisse, nelle stesse condizioni degli altri, un segnale rivelato più ampio; non si deve quindi andare a guardare il decimo di milliVolt in più o in meno. Inoltre può essere accaduto che, per i diodi dei quali ne ho acquistato un solo esemplare, me ne sia capitato uno un po' sordo, ma non è detto che questa sia una prerogativa di quel particolare modello di diodo.

Dopo aver eseguito le misure ho guardato la tabella, ed il vincitore come miglior diodo rivelatore si è *rivelato* essere il... SMS7630-001! Meno male, dovrei dire, perché l'1N23A, l'MA423A e l'1N405A costano 15 euro l'uno! L' SMS7630-001 invece mi è costato solo 1 euro. In realtà questo era il risultato che speravo di ottenere, perché dimostra che, per realizzare un'ottima galena, possono andare bene dei diodi di moderna concezione, e che quindi non si deve andare alla ricerca di chissà quale esoterico surplus da chissà quale negozio e/o fiera.

Diodo	Segnale rivelato $[mV_{eff}]$		
	primo	secondo	terzo
1N82A	0.80	0.85	-
AA137	0.35	0.35	0.30
DDC2353	1.00	0.97	-
ND4991	1.00	0.97	-
SMS7630-001	1.50	1.50	-
AAY30	0.28	0.30	0.32
BAT17-04	0	0	0
AA114	0.10	0.15	0.10
OA95	0.10	0.10	-
1N914	0	0	-
1N618	0.15	-	-
1N76A	0.80	-	-
1N23A	0.80	-	-
MA423A	0.70	-	-
1N405A	0.87	-	-

Tabella 1: Misure del segnale rivelato con i diodi.

Guardando poi i datasheet dei diodi della Tabella 1 risulta chiaro perché l'SMS7630-001 sia il migliore: è quello che presenta la più bassa tensione di soglia, ma anche la più bassa tensione inversa! Cosa che mi ha costretto ad aggiungere un 1N4148 in parallelo all'uscita. Ho aggiunto questo diodo dopo aver fatto "il servizio fotografico" alla radio, ed è per questo motivo che non è presente nelle foto.

4. Taratura e messa a punto

Per poter sintonizzare tutta la gamma FM bisogna eseguire una piccola taratura agendo sul trimmer tubolare. Per fare ciò ho aperto la scatola da uno dei lati, come in Figura 21, ho collegato l'uscita dell'oscillatore modulato ad un filo di un metro circa, che poi ho avvicinato all'antenna. Dopo aver impostato lo strumento per generare un segnale modulato di $87MHz$, con il condensatore variabile tutto chiuso, ho avvitato il trimmer con un tubetto di colla termica, per non toccarlo con le mani, fino ad ottenere il massimo segnale in cuffia. Il ricevitore è così tarato e "pronto all'uso".

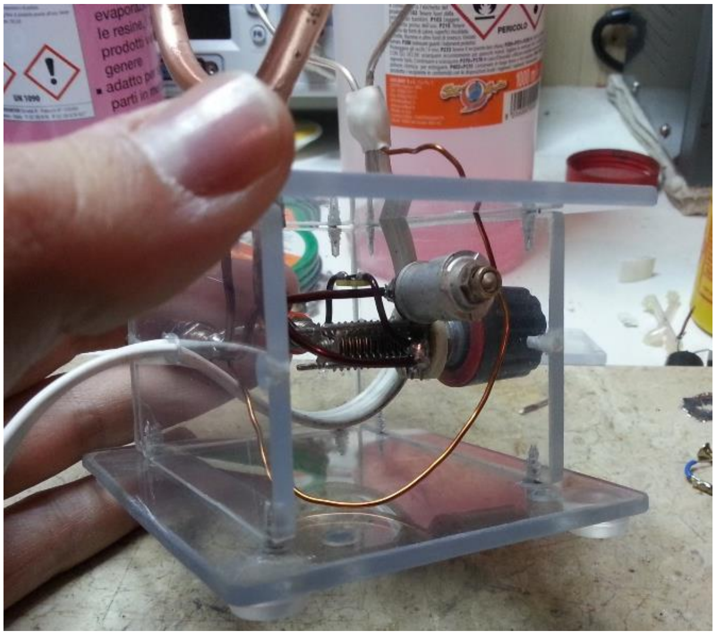

Figura 21: Taratura del ricevitore.

5. Prova d'ascolto

Usare la radio è molto semplice; basta montare l'antenna come per esempio in Figura 6, collegarla alla radio avendo cura di posizionare in orizzontale il cavo di discesa, cosicché non possa fungere da seconda antenna, calzare le cuffie e ruotare il condensatore variabile. Separare le stazioni interferenti è sempre possibile grazie al sistema di accoppiamento tra la bobina d'antenna e quella di sintonia, che permette di posizionarle anche ad angolo retto e ad una distanza di ben $5cm$, come è possibile notare nelle foto di Figura 22 e Figura 23.

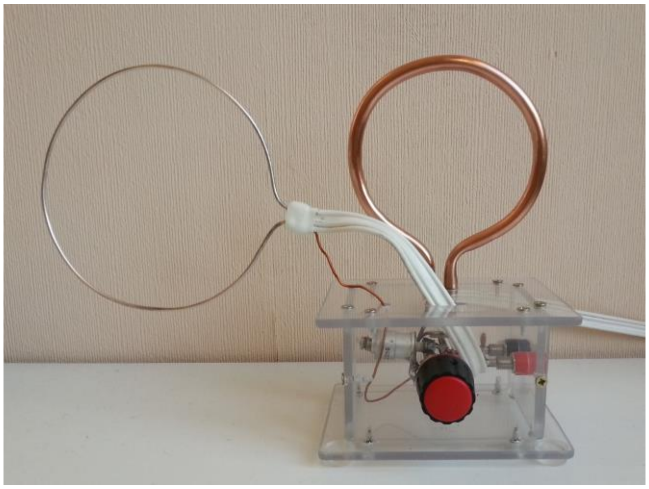

Figura 22: Esempio di accoppiamento lasco ottenibile tra le bobine L1 e L2.

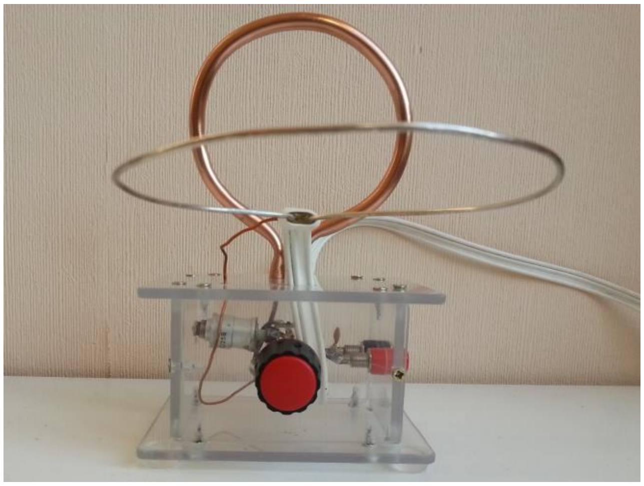

Figura 23: Esempio di accoppiamento minimo ottenibile tra le bobine L1 e L2.

I risultati ottenuti variano molto in base alla posizione del radiotecnico rispetto all'antenna ed all'installazione del dipolo ripiegato. In ogni caso con l'antenna montata nella mia stanza sono riuscito a ricevere un paio di stazioni, la più forte delle quali aveva un'ampiezza di circa $60mV_{pp}$. Con la stessa antenna sono riuscito a ricevere quattro stazioni collegando al posto delle cuffie un amplificatore. Con un'installazione migliore, sul balcone, sono riuscito a ricevere cinque stazioni, tre delle quali ben udibili.
Chi non ha già sperimentato con una radio a galena non può immaginare la gioia di poter ascoltare delle stazioni in lingua italiana, a qualsiasi ora del giorno e senza il bisogno del classico impianto antenna-terra. Un'antenna lunga almeno 10 metri è spesso difficile da installare, mentre una buona presa di terra è spesso impossibile da trovare, e puntualmente costringe il radiotecnico a posizionarsi in un punto scomodo della propria abitazione sia durante le sperimentazioni che durante le sessioni d'ascolto. Con un'antenna compatta come il dipolo ripiegato, che include anche la presa di terra, la radio a galena diventa un'oggetto portatile, come in effetti lo è sempre stato il circuito del ricevitore in sé. Sperimentare con le VHF può essere sicuramente difficile ma, a conti fatti, credo proprio che i vantaggi ottenuti compensino ampiamente le avversità con le quali ogni sperimentatore è chiamato a scontrarsi.
Con questo non mi resta che augurarvi un buon ascolto con tante sperimentazioni attorno ad una galena simile alla mia e alle altre già presentate su questo sito, sperando di esservi stato d'aiuto nel darvi molte idee per la realizzazione, e che la mia galena, insieme alle altre, vi abbia convinto ad avventurarvi in questa difficoltosa quanto gratificante impresa.

Just for Fun: Crystal Radios

Many years ago, one of my sons asked how a radio worked, and I suggested that the best way to answer his question was for us to build a crystal radio, as I had when I was about his age. As it turned out, it wasn't quite as easy as I had remembered, largely because some of the key components are much harder to find now. But, we found the parts, had a lot of fun and learned some things.

A couple of years after we built our first radio, we learned about a great organization, the X-tal Set Society (http://www.midnightscience.com). The Society has a web site, publishes books and a newsletter with lots of plans, and sells many of the hardest to find parts, as well as complete kits. If you are at all interested in crystal radios, be sure to visit the web site and buy some books and parts!

Here is some of what we learned and plans for the radio we came up with:

What does this have to do with proteins?

The truth is that many distinguished protein scientists have had very successful careers without knowing much about crystal radios! But, there is a bit of a connection. NMR spectroscopy, which is one of the most powerful modern tools for studying protein molecules, uses some of the same technology as radio communication. In fact, the circuitry of an NMR probe is almost identical to that of the tuning circuit for a radio, as described below.

Now, this may not be a sufficient motivation for you to learn about crystal radios, especially if you found this web site in the hopes of learning something about proteins. In this case you should probably take a look at some of our scientific publications (publications.html).

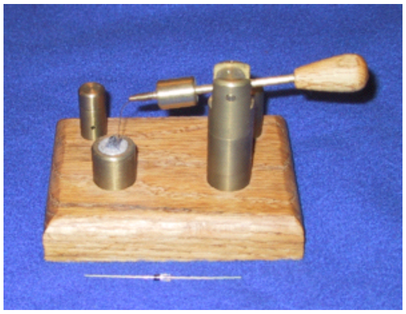
Introduction

The distinguishing feature of a crystal radio is that it requires no electric power: The sound is generated from the energy of the radio waves themselves, without any amplification. The audio signal is weak and is only powerful enough to drive earphones, but the sound can be wonderfully clear.

In the early years of the 20th century, crystal sets were the first radios in many homes. Even after radios with vacuum tubes (and then transistors) became widely available and relatively inexpensive, building a crystal radio was a very common introduction to electronics for many kids.

The Crystal

As suggested by the name, the key component is a crystal. Originally, the crystal was a mineral called galena. When a metal wire is brought into contact with galena, a rectifying junction is formed. That is, electricity flows through the connection with lower resistance in one direction than in the other direction. This provides a way of converting the high frequency AM radio signal into the much lower frequency audio signal that is then converted into sound in the earphones. Extracting the audio signal from the modulated radio signal is called "detection", and the crystal with the wire that touches it (called a "cat's whisker") is a "detector". The picture below shows a crystal detector I built, along with its modern equivalent, the diode.



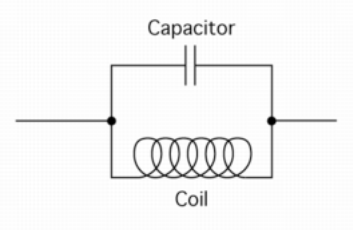
This is not an exact reproduction of an antique detector, but it is similar in style and serves the same functions of holding the crystal steady and allowing the cat's whisker to be carefully positioned. Not every position on the crystal will work, and it takes lots of patience to find a good spot and carefully adjust the cat's whisker for the best signal. Each crystal is different, and some work better than others. When radios were first installed on ships, each operator would often have his own favorite crystals that he would carry with him from one ship to another.

In the 1920's crystal detectors were largely replaced with vacuum tubes, which amplified the signal as well as detected it. During World War II, however, the crystal detector was brought back to prominence as a key component in the very high frequency circuits necessary for radar. Through a great deal of fundamental research in solid-state physics, methods were developed to reliably produce efficient detectors that did not require any of the fiddly adjustment of the original devices. Solid-state diodes became essential components of nearly all electronic devices, and most crystal sets are now built using readily available germanium diodes, like the one shown above. (A package of 10 can be bought at Radio Shack for about a dollar.) If, though, you would like to build a radio with a real crystal, galena crystals and wire for the cat's whisker can be purchased from the X-tal Set Society.

After World War II, the diode and the knowledge of solid state physics that was gained in developing it became the basis for the first transistors. Transistors, in turn, led to integrated circuits, and integrated circuits, of course, led to inexpensive computers and all of the other electronic marvels we now take for granted. The simple crystal detector is the direct ancestor of modern solid-state electronics.

The Tuning Circuit

The second major requirement for a radio receiver is a means of separating out signals with different frequencies, i.e. tuning in different stations. The simplest efficient circuit for this purpose consists of just a coil of wire and a capacitor connected in parallel, as shown below using the standard symbols for electronic components.

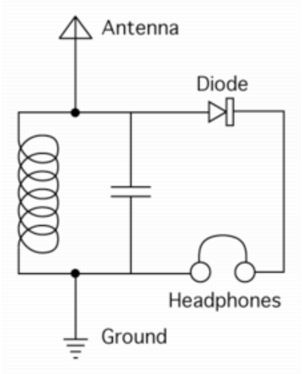


Typically, the coil for a crystal radio is formed by wrapping a single layer of enamel-coated copper wire over a cardboard or plastic tube a few inches long and an inch or two in diameter. The coil has a very important electronic property: Although direct current passes through it with low resistance, its resistance to a current that rapidly changes direction (an alternating current) increases as the frequency of the reversals increases. (The resistance to an alternating current is more properly called "impedance".) The impedance depends on the dimensions of the coil and the frequency of the current.

As indicated by its schematic symbol, a capacitor in its simplest form is composed of two metal plates separated by air or some other non-conducting material. This may seem like an odd arrangement for an electronic component, since it doesn't look as though electricity could pass through it. Indeed, direct current can't. But, an alternating current can. The impedance of a capacitor decreases as the frequency increases; exactly the opposite of the effect of a coil.

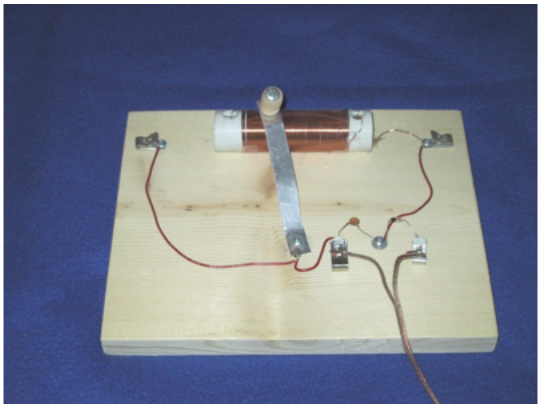
Now, think about what would happen if the circuit was connected to currents of different frequencies. At a very low frequency, the current will pass readily through the coil, but not the capacitor. At very high frequencies, the current passes through the capacitor but not the coil. For a given combination of coil and capacitor, there will be a magic frequency at which the impedance of the circuit is a maximum. At this frequency, electrical charge alternately builds up on the two plates of the capacitor and flows back and forth through the coil. The circuit is said to "resonate", just as a weight on a spring will resonate at a characteristic frequency.

In a radio, one side of the tuning circuit is connected to an antenna. For maximum efficiency, the other side of the circuit is connected to a metal rod or pipe buried in the ground. Radio waves are converted into alternating electrical currents in the antenna. Signals with frequencies that are higher or lower than the resonant frequency pass through the tuning circuit to the ground. (If the radio has a means of amplifying the weak signal from the antenna, as all modern radios do, the ground connection isn't necessary.) If, however, there is a signal that matches the resonant frequency, the energy of this signal can be drawn off to create the audio signal. In a simple crystal radio, the crystal detector and headphones are connected to the tuning circuit as shown below:

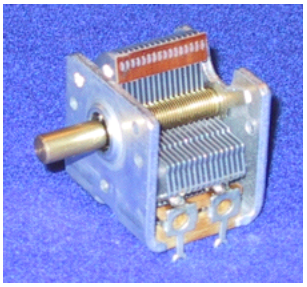


Detailed instructions for building a radio based on this circuit can be found below.

If the radio is to receive signals of more than one frequency, there has to be a means of adjusting either the coil or the capacitor. An adjustable coil can be made by scraping the enamel insulation off of the wire along a section of the coil running along its length and then arranging a slider that can be moved to contact the coil wire at different points. This is the method used in our radio, as shown in the picture below:



There are also adjustable capacitors. These usually have two sets of metal plates, one of which is mounted on a shaft that is turned to adjust the overlap between the two sets, as shown below:



Capacitors suitable for AM radios aren't so easy to find anymore, but the X-tal Set Society (http://www.midnightscience.com/catalog5.html) has found someone to manufacture them, and they are available for a quite reasonable price. Using one of these, you can build a crystal radio without having to make a slider, or you can build a set with both components adjustable. The latter option makes it possible to cover a wider range of frequencies and can increase the sensitivity of the set.

Headphones

The final critical component of a crystal set is a suitable earphone or pair of headphones. This isn't a easy as it might appear: The readily available headphones for portable radios, tape players, CD players, etc. won't work. At all. The reason is that these modern headphones are designed to be used with amplifiers and have a low impedance. A crystal set requires an earphone with a high impedance to match the other components of the circuit.

There are two major alternatives. The least expensive is a small earphone that uses a piezo-electric crystal to convert the electrical signal into sound. Most earphones in stores are not of this type, but crystal earphones can be found at some shops that sell electronic parts for hobbyists or ordered from the X-tal Set Society, as shown on the left in the picture below:

This type of earphone is found in most inexpensive crystal radio kits. Some seem to work better than others.

Better results can be obtained using a pair of high-impedance electromagnetic headphones, as shown on the right side of the figure above. These used to be quite common, but, like variable capacitors, are much less so now. But, you may be able to find a pair in someone's attic or at an Army-Navy Surplus store. I bought the pair shown above at a surplus store in San Diego. Suitable headphones will have a DC resistance, which you can measure with a simple Ohm meter, of about 2000 Ohms. With a good set of headphones, the sound from a crystal set can be plenty load and surprisingly clear.

Plans

Here are instructions for building the crystal radio shown above, in a pdf (Adobe Acrobat) file: Crystal Radio Instructions (./downloads/radioInstructions.pdf)

These instructions were included in a book entitled "Crystal Radio Projects" (http://www.midnightscience.com/projbook.html) published by the X-tal Set Society. The book includes lots of other radio plans, most of which are more elaborate than this one.

KEVIN'S WEBSURFER HANDBOOK V
FOR CRYSTAL RADIO

INDUCTANCE, INDUCTORS and MEASURING Q

Kevin Smith
2013

NOTES:

NOTES:

INTRODUCTION

Finally, I have cobbled together a handbood dedicated to that one crystal radio component virtually all builders fabricate for themselves, the coil. This has been a long time in comming together. As I have increased my knowledge of set design and theory, I have found a deeper need for good technical background reading. Inductors, as will quickly be found, are highly mathematical beasties. Their properties, those we most wish to know such as Quality (Q), Resistance, Losses, etc are devilishely difficult to measure. As such, I have not spent as much time digging into this as I have for diodes, antennas, grounds etc.

I gather together in this volume articles with the central theme of inductance. Some of these are introductory and have appeared in earlier handbooks, others are specialized and will be found here alone. I wish to include both theory as well as practical articles on their design and construction. As an addition, you will find two non-crystal radio projects which otherwise rely on induction and induction coils for their performamce. These describe a cool VLF-ULF coil. Hopefully this volume gives the crystal set designer / builder a good base of understanding for this chief set component.

Of general note, the web is a marvelous source of data and information. Many long-time crystal set builders, and many others have created dedicated sites to disseminate information and resources, to share their creations and knowledge. I am eternally in your debt. All of the material in this handbook is copyright for which I have not sought permission. Therefore this is not presented for publication or copy. It is only my personal resource. I encourage anyone finding this copy to pursue ON THE WEB the web pages identified within. I include the name of the author and web address of each section. I wish to sincerely thank every author presented for their excellent pages and ask forgiveness for my editing into this handbook.

2013

www.lessmiths.com/~kjsmith/crystal/cr0intro.shtml

By the way, the speakers sound terrific! I'm not sure how much of the improvement was from the litz wire, but it certainly didn't hurt the sound!

I tried several of these methods, and none were satisfactory in producing a nice clean tinned wire end, without breaking or damaging the strands. However, I did eventually come up with a simple, fast and very effective method, so I thought I would share it with the other DIY'ers here, in case they are crazy enough to build something with litz wire.

A Dremel tool with a stainless steel wire wheel attachment works very well. I found that the stainless wheel works faster and lasts longer than the carbon steel wheel, with the added advantage that the small pieces of the wheel brush that wear off during the process are non-magnetic, so they won't attach to nearby driver magnets (don't need little pieces of wire inside my EMIMs and EMITs!). Simply remove ~ 1/2" of the insulation, then untwist the various strands from each other (the Cardas Litz has 3 counterwound layers of different diameter wire to untwist, do them one at a time) and flatten them into a flat fan shape. Set the Dremel to about 1/2 of maximum speed and apply to the coated wire, ensuring that the wheel is ALWAYS turning toward the ends of the wire (otherwise they will entangle with the spinning wire wheel and snap off!). 10 seconds on each side of the fanned wire is very effective at removing the varnish coating without destroying the wires. Then re-fan the wire in a different direction and repeat the process 2 or 3 times to ensure that all the wires get stripped. You will be left with nice clean varnish-free wires, which can then be tinned as usual.

As a test of this method I measured the AC impedance of each of the wires of the same length at 10kHz using my LCR meter, and found that they all were very consistent, indicating that I was effectively and consistently removing the varnish and using all the wires in the bundle.

Litz Wire - Here's the Best Way I've Found to Prep

Maxamillion
http://www.audiokarma.org/forums/archive/index.php/t-282190.html

I just completed building outboard crossovers for my Infinity RSIIb speakers, and I was determined to wire the crossovers together and to the speakers using Cardas Copper Litz wire, due to its flatter AC impedance as frequencies increase. The Cardas Litz wire consists of many fine strands of wire, each individually insulated, which all need to be stripped and tinned together at each end in order to form a proper termination. Quite a job!

I searched the literature for methods and there were many, including:

1) The use of a solder pot at >800 degrees (too expensive to purchase one just for this project),

2) Using a hot soldering iron and lots of flux (very, very messy and very, very ineffective in my case!),

3) Scraping the coating off with an exacto knife, (not attempted due to the tedium factor),

4) Burning the coating off with a torch, followed by sanding (I found it works, but you end up oxidizing the wires and even incinerating some of the smaller strands),

5) Individually sanding each strand (I'd be doing this job for years as each wire has dozens of strands and I have 6 tweeters, 6 midranges and 4 woofers to wire up to 18 capacitors and 20 inductors!).

DESIGNING AN AIR-CORE INDUCTOR

by Kenneth A. Kuhn
http://www.kennethkuhn.com/students/crystal_radios/designing_inductors.pdf

Introduction

This chapter describes the mathematical process for designing an air-core inductor comprised of a single layer solenoid winding over a rigid coil form. Although the development of the mathematics is a bit complicated the final result is simple to apply. For practical reasons, this chapter will make use of English rather than metric units. A well designed and constructed air-core coil has better performance than those with ferrite cores. Ferrite acts as a flux multiplier and has the advantage that the physical size of the inductor can be reduced. That is very important for small radios and the chief reason ferrite is used. The price paid for small size is loss of performance but that loss is generally negligible in active radios. The loss is not bad for crystal radio performance and many good crystal radios have been built using ferrite core inductors. But ferrite is not required. Purists correctly argue that the coil should be air core as that is how early radios were built. A mediocre ferrite core inductor will work considerably better than a poorly designed air-core one and that has probably led to the popularity of ferrite as the process for designing good air-core inductors is not widely known. This chapter reveals those secrets.

Analytic equation

The classic equation (which you can find in any book or article about winding inductors) for calculating the inductance of a given single layer coil is (Reference 2):

$$L = \frac{r2*n2}{9*r + 10*l} \qquad \text{Eq. 1}$$

where:
L = inductance in microhenries
r = coil radius in inches (center of coil to center of conductor)
n = number of turns
l = coil length in inches (center of starting turn to center of ending turn)

This equation is generally accurate to around one percent for inductors of common dimensions. It is more convenient to work with coil diameter and Equation 1 can be written as:

$$L = \frac{d2*n2}{18*d + 40*l} \qquad \text{Eq. 2}$$

where d is the coil diameter in inches (center of conductor to center of conductor)

Example: What is the inductance of a coil has a diameter of 2.5 inches, a length of 2.33 inches, and has 72 turns?

$$L = \frac{2.5*2.5*72*72}{18*2.5 + 40*2.33} = 234 \text{ uH}$$

Development of design equations

Equations 1 and 2 are fine for determining the inductance of an existing coil but are very awkward to apply to the design of a desired coil as there are many variables. Any time there are a multitude of variables then the possibility of optimum combinations or relations should be explored. In the following development the number of variables is reduced by finding

When the coefficient of coupling, k is equal to 1, (unity) such that all the lines of flux of one coil cuts all of the turns of the other, the mutual inductance is equal to the geometric mean of the two individual inductances of the coils. So when the two inductances are equal and L_1 is equal to L_2, the mutual inductance that exists between the two coils can be defined as:

$$M = \sqrt{L_1 L_2} = L$$

Example No1

Two inductors whose self-inductances are given as 75mH and 55mH respectively, are positioned next to each other on a common magnetic core so that 75% of the lines of flux from the first coil are cutting the second coil. Calculate the total mutual inductance that exists between them.

$$M = k\sqrt{L_1 L_2}$$

$$M = 0.75\sqrt{75\text{mH} \times 55\text{mH}} = 48.2\text{mH}$$

In the next tutorial about Inductors, we look at connecting together *Inductors in Series* and the affect this combination has on the circuits mutual inductance, total inductance and their induced voltages.

---

relations to known constants. We first replace the coil length by a factor that relates it to the diameter.

l = k*d Eq. 3

where
l = coil length in inches
k = a dimensionless constant
d = coil diameter in inches as before
Substituting Equation 3 into Equation 2 gives:

```
          d2*n2
L = ---------------------
     18*d + 40*k*d
```

which reduces to

```
        d*n2
L = --------------          Eq. 4
     18 + 40*k
```

It can be shown that the value of k that minimizes the length of wire to wind the coil is 0.450. However, other research indicates (see Reference 1) that the value of k that minimizes coil losses is approximately 0.96 even though that value uses about twenty percent more wire. Factors contributing to coil losses include:

- * Ohmic losses in the wire including skin-effect
- * Dielectric losses in the coil form and nearby materials
- * Dielectric losses in the insulation around the wire
- * Induction losses in nearby materials

There are also losses caused by adjacent turns being too close together. It has been found (see Reference 1) that the optimum spacing (wire center to wire center) of adjacent turns is between about 1.3 to 2.0 times the diameter of the conductor. Coils for crystal radios are commonly wound using what is known as magnet wire (thin enamel insulation) and the turns are tightly wound next to each other corresponding to a spacing factor slightly greater than 1.0 (the thin insulation is of finite thickness). Although it is less than the optimum discussed it works well.

Without some special technique (such as a lathe) it can be very difficult to manually wind a coil with controlled spacing between the turns. One easy method for achieving a spacing factor of 2.0 is to wind two wires tightly side by side at the same time and then remove one of the windings when finished. Smaller spacing factors can be achieved using a smaller diameter wire for the spacer but the difficulty of controlling two wires will increase. It might occur to someone to use a wire with a thicker insulation so that a spacing is naturally formed with a tight winding. The problem with this method is that the insulation may increase dielectric losses and become self defeating –although this may be a small issue –be sure to try it before tossing the concept. This method can work great if Teflon wire is used as that is a very low-loss material and the internal wire strands are silver plated.

Equation 4 can be used to determine the optimum coil diameter for a given inductance and wire size. We note that the coil length is the number of turns divided by t (turns per inch of the wire). We also note that the coil length has previously been related to the coil diameter by the constant, k. Thus:

n = k*d*t Eq. 5

Substituting Equation 5 into Equation 4 gives:

However, the above equation assumes zero flux leakage and 100% magnetic coupling between the two coils, L_1 and L_2. In reality there will always be some loss due to leakage and position, so the magnetic coupling between the two coils can never reach or exceed 100%, but can become very close to this value in some special inductive coils. If some of the total magnetic flux links with the two coils, this amount of flux linkage can be defined as a fraction of the total possible flux linkage between the coils. This fractional value is called the **coefficient of coupling** and is given the letter k.

Coupling Coefficient

Generally, the amount of inductive coupling that exists between the two coils is expressed as a fractional number between 0 and 1 instead of a percentage (%) value, where 0 indicates zero or no inductive coupling, and 1 indicating full or maximum inductive coupling. In other words, if $k = 1$ the two coils are perfectly coupled, if $k > 0.5$ the two coils are said to be tightly coupled and if $k < 0.5$ the two coils are said to be loosely coupled. Then the equation above which assumes a perfect coupling can be modified to take into account this coefficient of coupling, k and is given as:

Coupling Factor Between Coils

$$k = \frac{M}{\sqrt{L_1 L_2}} \text{ or } M = k \text{ x } \sqrt{L_1 L_2} \quad H$$

the size, number of turns, relative position or orientation of the two coils. Because of this, we can write the mutual inductance between the two coils as: $M_{12} = M_{21} = M$.

Hopefully we remember from our tutorials on *Electromagnets* that the self inductance of each individual coil is given as:

$$L_1 = \frac{\mu_o \mu_r N_1^2 A}{\ell} \text{ and } L_2 = \frac{\mu_o \mu_r N_2^2 A}{\ell}$$

Then by cross-multiplying the two equations above, the mutual inductance that exists between the two coils can be expressed in terms of the self inductance of each coil.

$$M^2 = L_1 L_2$$

giving us a final and more common expression for the mutual inductance between two coils as:

Mutual Inductance Between Coils

$$M = \sqrt{L_1 L_2} \quad H$$

$$L = \frac{k2*t2*d3}{18 + 40*k} \qquad \text{Eq. 6}$$

We will use 0.96 for k and t will be that of the particular wire we have available. Solving Equation 6 for the optimum diameter gives:

$$d\_optimum = 4*(L/t2)1/3 \qquad \text{Eq. 7}$$

Figure 1 shows a plot of this Equation 7 for common wire sizes. In all cases the turns are close-spaced. The lower curves are for common enamel insulated magnet wire. The two upper curves are for vinyl insulated house wire which can be considered if a large diameter coil form is available. To use the curves, select the desired inductance and the wire size that will be used. Look up the optimum coil form diameter and then use the closest practical form you have to that size. The optimum is broad so do not worry about being exactly on it. Note that the true diameter is the sum of the diameter of the coil form and the diameter of the wire since by definition the coil diameter is measured between opposite centers of the wire.

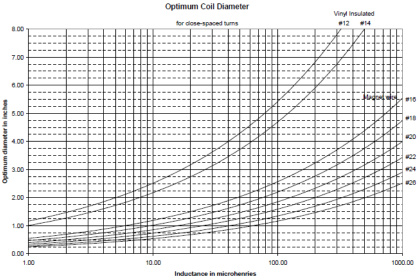

Figure 1: Optimum coil diameter

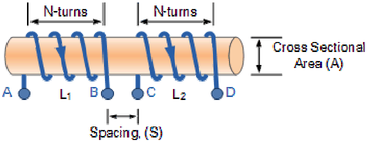
The following table provides typical values for t (turns per inch) for some common wire sizes:

Table 1: Wire data

Gauge	t	Comments
12	6.2	Vinyl insulated house wire
14	7.7	Vinyl insulated house wire
16	19	Enamel insulated magnet wire
18	24	ditto
20	31	ditto
22	39	ditto
24	50	ditto
26	62	ditto

The length of the winding will be the number of turns divided by the turns per inch of the wire. That is:

Mutual Induction



Here the current flowing in coil one, L_1 sets up a magnetic field around itself with some of these magnetic field lines passing through coil two, L_2 giving us mutual inductance. Coil one has a current of I_1 and N_1 turns while, coil two has N_2 turns. Therefore, the mutual inductance, M_{12} of coil two that exists with respect to coil one depends on their position with respect to each other and is given as:

$$M_{12} = \frac{N_2 \Phi_{12}}{I_1}$$

Likewise, the flux linking coil one, L_1 when a current flows around coil two, L_2 is exactly the same as the flux linking coil two when the same current flows around coil one above, then the mutual inductance of coil one with respect of coil two is defined as M_{21}. This mutual inductance is true irrespective of

The mutual inductance that exists between the two coils can be greatly increased by positioning them on a common soft iron core or by increasing the number of turns of either coil as would be found in a transformer. If the two coils are tightly wound one on top of the other over a common soft iron core unity coupling is said to exist between them as any losses due to the leakage of flux will be extremely small. Then assuming a perfect flux linkage between the two coils the mutual inductance that exists between them can be given as.

$$M = \frac{\mu_0 \mu_r N_1 N_2 A}{\ell}$$

- Where:
- μ_o is the permeability of free space ($4.\pi.10^{-7}$)
- μ_r is the relative permeability of the soft iron core
- N is in the number of coil turns
- A is in the cross-sectional area in m^2
- l is the coils length in meters

---

l = n/t Eq. 8

We now substitute Equation 8 into Equation 2 and solve for n

d2*n2 –18*d*L –40*(n/t)*L = 0 Eq. 9

t*d2*n2 –40*L *n –18*d*t*L = 0 Eq. 10

Solving for n gives:

$$n = \frac{20*L + sqrt(400*L2 + 18*t2*d3*L)}{t*d2} \qquad \text{Eq. 11}$$

Although a precise value (in inches) for the length of wire required can be calculated using trigonometry for a spiral, a very close value can be calculated as

w = pi*d*n Eq. 12

Remember that d is the sum of the coil form diameter and the diameter of the wire. This approximation assumes that the diameter of the wire is very small in comparison to that of the coil form. Also remember to allow an extra couple of inches for connecting leads at each end of the coil.

Example: A 300 uH coil is needed. The expected Q should be over 350. What coil diameters and wire sizes could possibly meet this?
Solution: Using Figure 2 it can be seen that wire sizes #12, #14, #16, #18, and #20 could achieve the required Q. Using Figure 1 the required coil form diameters are:

Optimum

Gauge	diameter
#12	7.75”
#14	6.75”
#16	3.75”
#18	3.15”
#20	2.65”

A piece of 4.5” OD PVC pipe is available and #14 electrical wire is available. From Table 1, #14 insulated wire will make about 7.7 turns per inch. Thus, the effective diameter is 4.5 plus 1/7.7 = 4.63 inches. Using Equation 11 the number of turns required is 86. Using Equation 8 the length of the winding is 11.2 inches. The length/diameter ratio is 2.4 which is a bit longer than the optimum of 0.96. The length of wire required is given by Equation 12 and is 1,251 inches. The length would have been 1,058 inches if the optimal diameter could have been used. This extra length will cause somewhat higher losses –it might still meet the desired spec though. This is about as far as I would go in rounding to an available coil form diameter.

Estimation of Inductor Q

All inductors have an equivalent series resistance loss as discussed earlier and is comprised of a number of components. We measure the quality factor or Q of the inductor by computing the ratio of inductive reactance at the frequency of interest to the series loss resistance as follows:

$$Q = \frac{XL}{Rs} \qquad \text{Eq. 13}$$

where

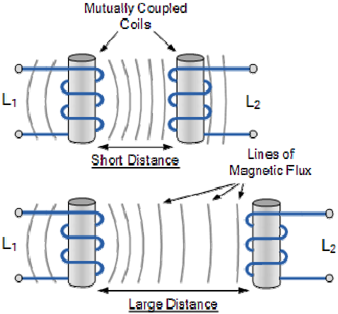
Q is the dimensionless “quality” factor of the inductor

---

magnetic flux generated by the first coil will interact with the coil turns of the second coil inducing a relatively large emf and therefore producing a large mutual inductance value.

Likewise, if the two coils are farther apart from each other or at different angles, the amount of induced magnetic flux from the first coil into the second will be weaker producing a much smaller induced emf and therefore a much smaller mutual inductance value. So the effect of mutual inductance is very much dependant upon the relative positions or spacing, (S) of the two coils and this is demonstrated below.

Mutual Inductance between Coils



Mutual Inductance of Two Coils

Wayne Storr

http://www.electronics-tutorials.ws/inductor/mutual-inductance.html

In the previous tutorial we saw that an inductor generates an induced emf within itself as a result of the changing magnetic field around its own turns, and when this emf is induced in the same circuit in which the current is changing this effect is called **Self-induction**, (L). However, when the emf is induced into an adjacent coil situated within the same magnetic field, the emf is said to be induced magnetically, inductively or by **Mutual induction**, symbol (M). Then when two or more coils are magnetically linked together by a common magnetic flux they are said to have the property of **Mutual Inductance**.

Mutual Inductance is the basic operating principal of transformers, motors, generators and any other electrical component that interacts with another magnetic field. Then we can define mutual induction as the current flowing in one coil induces an emf in an adjacent coil. But mutual inductance can also be a bad thing as "stray" or "leakage" inductance from a coil can interfere with the operation of another adjacent component by means of electromagnetic induction, so some form of electrical screening to a ground potential may be required.

The amount of mutual inductance that links one coil to another depends very much on the relative positioning of the two coils. If one coil is positioned next to the other coil so that their physical distance apart is small, then nearly nearly all of the

XL is the inductive reactance in ohms at the frequency of interest

Rs is the equivalent series resistance in ohms at the frequency of interest

Note that inductive reactance, XL, is calculated as

$XL = 2*\pi*F*L$

where

F is the frequency in Hz

L is the inductance in henries

The equivalent series resistance is the net of ohmic losses including skin effect, dielectric losses in distributed capacitance and coil structure, absorption losses by nearby conducting media, magnetic losses in nearby magnetic media, etc. With care these losses can be kept small but it takes very little loss to reduce the Q of an inductor from 400 to 200. The magnitude of Rs can be measured on sophisticated impedance equipment but it is hard to calculate the effect of all factors. Figure 2 shows an estimated value of Q at 1 MHz considering typical losses assuming the coil is wound optimally and is not disturbed by nearby lossy materials. Use the figure only as a guideline as your specific results may be better or worse. The expected Q at 540 kHz will be between about 50 to 70 percent of what is shown and the expected Q at 1.6 MHz will be around 1.2 to 1.5 times that shown.

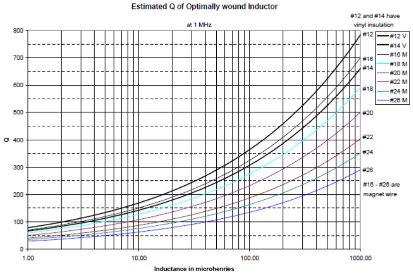


Figure 2: Estimated Q of Inductor

The Q we obtain from Equation 11 is for the unloaded coil (i.e. antenna and crystal detector not connected). The net loaded Q will typically be significantly smaller but ideally (as discussed in another chapter) would be in the general range of one hundred. Thus, we would like to start with an unloaded Q of several hundred. As can be seen in Figure 2 the Q of the inductor can be made higher by using larger diameter wire. From Figure 1 this also means using a large diameter coil form. This is a very important conclusion –high Q coils need to be physically large.

Type of wire

The only material to consider for the wire is copper. A variety of styles of copper wire is readily available. The most basic choice is between solid or stranded. Although a variety of arguments can be made for and against each, in practical terms you will not notice any difference in performance although one

---

The power delivered to an ideal transformer[2] on its primary circuit will match the power output on its secondary circuit and we can write $I_p V_p = I_s V_s$ or

$$\frac{I_s}{I_p} = \frac{V_p}{V_s} = \frac{N_p}{N_s}$$

---

[2] Here we neglect the resistances of the windings and the energy expended in magnetizing and demagnetizing the iron core.

$$E_s = -N_s \frac{\Delta\Phi}{\Delta t}$$

In the primary coil the induced emf is due to self-induction and is given by Faraday’s law as

$$E_p = -N_p \frac{\Delta\Phi}{\Delta t}$$

The term $\Delta\Phi/\Delta t$ is the same in both equations since the same amount of magnetic flux Φ passes through both coils. Dividing the equations gives

$$\frac{E_s}{E_p} = \frac{N_s}{N_p}$$

If the resistances of the coils are negligible the terminal voltages V_s and V_p of the coils are nearly equal to the magnitudes of the emfs E_s and E_p. Hence we can write

$$\boxed{\frac{V_s}{V_p} = \frac{N_s}{N_p}}$$

This is called the ***transformer equation***.

or the other may have physical advantages for your particular construction method. Avoid wires that are plated as those will have higher losses since skin-effect will cause most of the conduction to be in the plating which has higher resistance than copper. Avoid wires with rubber or cheap plastic insulations as dielectric losses will be higher. An exception is silver plated Teflon wire as that has the best conductivity and the lowest dielectric losses –but it is expensive.

For use in low to medium frequency inductors there is a special wire called Litzengrad or just Litz for short. It is designed to minimize skin-effect losses and is made by assembling many strands of enamel insulated magnet wire together to form a wire that has a large surface area. Litz wire is not easy to find and tends to be expensive. If you are going to use Litz wire then make sure that other losses as previously discussed are minimized. Otherwise Litz wire will make little if any difference and will be wasted effort and expense. Avoid belief in a variety of myths about skin-effect. Although it is true that skin-effect is more severe on large diameter conductors, a larger diameter still conducts better than a smaller diameter at any frequency. This can be seen in Figure 3 which shows the frequency dependence of the resistance per meter factor of some common wire sizes.

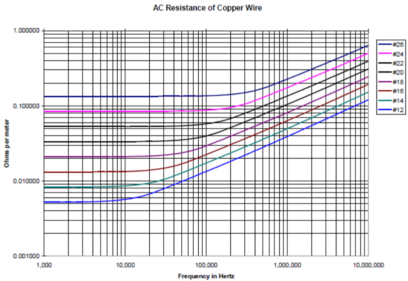

Figure 3: AC Resistance of Copper Wire

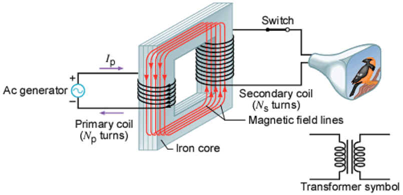
Coil Forms

From a loss standpoint air is the best coil form material there is. The obvious problem is that air has no structural strength. However, there are methods used by commercial inductor companies that employ a minimal structure so that the coil form is around 99 percent air. Manually, you can achieve the effect by first winding the coil using large diameter solid copper wire (i.e. #18, #16, #14, etc.) on a rigid coil form and then carefully sliding the winding off of the form. The stiff wire will retain the shape and you can easily space the turns to the optimal discussed previously. You will need a few supports to keep the whole thing from being too loose.

A popular coil form is some kind of cardboard tube that you have salvaged from a variety of sources such as used for paper towels or shipping tubes. These are great if you are using small diameter wire as small wire will not self support. Plastic pipe

Transformers



A ***transformer*** is a device for increasing or decreasing an AC voltage. It consists of an iron core with two coil wrappings: a primary coil with N_p turns and a secondary coil with N_s turns. See the figure at the right.

Assume an AC source, such as an AC generator, produces an alternating current I_p in the primary coil. The primary coil creates a changing magnetic flux Φ in the core which links the turns of both the primary and secondary coils.[1] In the secondary coil the induced emf arises from mutual induction and is given by Faraday's law as

---

[1] The details of the operation of a transformer, which also involve the magnetization and demagnetization of the iron core, is complex. Here we assume, for simplicity, a transformer operating in steady-state with a purely resistive load.

Assume that the solenoid carries a current I. Then the magnetic flux in the solenoid is

$$\Phi = \mu_0 \frac{NI}{l} A. \; L = \frac{N\Phi}{I} = \frac{N}{\cancel{I}} \mu_0 \frac{N\cancel{I}}{l} A$$

$$L = \mu_0 \frac{N^2}{l} A \text{ or } \boxed{L = \mu_0 n^2 A l} \text{ where } n = \frac{N}{l}.$$

(Note how L is independent of the current I.)

---

is another material you might consider. None of these materials are made with any consideration about high frequency dielectric losses but because only a small amount of material is used the losses are probably minimal.

Wood is a convenient coil form and has low losses if very dry. Common sizes that have been used are 2x2, 4x4, or a pair of 2x4 combined to make 4x4. Round dowel rods may also be used but their diameters are often much less than optimum. When using a square coil form there is a logical question about how that affects the inductance calculations. A simplistic (but good) answer is to use an effective circle diameter that has the same area as the square form since area is a strong factor in inductance. Losses with a square form will be somewhat higher than for a circular form. Rectangular forms (such as a single 2x4) have even higher losses in comparison –it takes more wire to encompass a given area.

Winding the coil

Counting turns is a tedious and error prone task. It is much simpler to cut the length of wire needed and then wind that until finished. The resulting turns count will be very close if not exact. Wire is springy and will jump off the form in a tangled mess if not restrained. Start by securing the wire at one end of the form and have a means for easily (preferably with one hand) securing the opposite end when you finish. It is tempting to use some kind of adhesive tape and that will work if you are careful and understand what you are doing. The forces will build and the tape may give way which will result in a frustrating mess of tangled wire. Make sure the tape can not slip. A good way to secure the ends is to first drill a hole in the tube at the starting and end points. Then feed the starting end through the starting hole and bend the wire such that it naturally resists tension and secure the wire with tape. Stuff the loose end length inside the tube so it is out of the way while winding.

It is best to wind the coil by hand as the set up for using a lathe is not worth the trouble for a single coil. There are a number of "poor man's" lathes such as a power drill that have been used but I do not recommend that as you are more likely to make a mess or cause injury than you are to wind a coil. It only takes a couple of minutes to wind a coil by hand so take the time to think what you are doing. It is important to keep the winding tight at all times. The wire will spring off if it ever gets loose. You will very likely have some fractional turn as a result of your calculations. I recommend that you round that to the nearest integer as it is not worth the trouble of making measurements to stop at a specific fractional turn.

Relay League, Newington, Conn., page 26

Let the coil have N turns. Assume that the same amount of magnetic flux Φ links each turn of the coil. The net flux linking the coil is then $N\Phi$. This net flux is proportional to the magnetic field, which, in turn, is proportional to the current I in the coil. Thus we can write $N\Phi \propto I$. This proportionality can be turned into an equation by introducing a constant. Call this constant L, the ***self-inductance*** (or simply ***inductance***) of the coil:

$$N\Phi = LI \quad \text{or} \quad L = \frac{N\Phi}{I}$$

As with mutual inductance, the unit of self-inductance is the henry.

The self-induced emf can now be calculated using Faraday's law:

$$\mathsf{E} = -N\frac{\Delta\Phi}{\Delta t} = -\frac{\Delta\left(N\Phi\right)}{\Delta t} = -\frac{\Delta\left(LI\right)}{\Delta t} = -L\frac{\Delta I}{\Delta t}$$

$$\boxed{\mathsf{E} = -L\frac{\Delta I}{\Delta t}}$$

The above formula is the ***emf due to self-induction***.

Example

Find the formula for the self-inductance of a solenoid of N turns, length l, and cross-sectional area A.

The above formula is the ***emf due to mutual induction***.

Example

The apparatus used in Experiment EM-11B consists of two coaxial solenoids. A solenoid is essentially just a coil of wire. For a long, tightly-wound solenoid of *n* turns per unit length carrying current *I* the magnetic field over its cross-section is nearly constant and given by $B = \mu_0 nI$. Assume that the two solenoids have the same cross-sectional area *A*. Find a formula for the mutual inductance of the solenoids.

The magnetic flux in the primary coil is

$\Phi_1 = \mu_0 \frac{N_1 I_1}{l_1} A$ where l_1 is the length of the primary coil.

$$M = \frac{N_2 \Phi_2}{I_1} \quad \text{But } \Phi_2 = \Phi_1 : \quad M = \frac{N_2 \Phi_2}{I_1} = \frac{N_2}{\cancel{I_1}} \mu_0 \frac{N_1 \cancel{I_1}}{l_1} A; \quad \boxed{M = \mu_0 \frac{N_1 N_2}{l_1} A}$$

(Note how M is independent of the current I_1.)

Self-Inductance

A current-carrying coil produces a magnetic field that links its own turns. If the current in the coil changes the amount of magnetic flux linking the coil changes and, by Faraday's law, an emf is produced in the coil. This emf is called a *self-induced* emf.

"Professor Coyle" Coil Calculators

By Dan Petersen

http://www.crystalradio.net/professorcoyle/index.shtml

Instructions for Professor Coyle:

Professor Coyle is intended to be a mathematical aid in determining the inductance of a coil and the resonant frequency of a coil-capacitor tuned circuit.

To Use The Coil Calculator:

The coil calculator will calculate the inductance of both closewound or non-closewound or "spaced" coils. To do a closewound coil, enter the coil diameter and the desired number of turns into the appropriate places. Left-click on any of the red numbers to change their value, then press <enter>. Look at the list below the entered numbers ans you will note a series of inductances and lengths paired with the gauge of wire to be used. These are the inductances and coil lengths of a closewound coil as a function of the wire guage. For example, enter a form diameter of 1.75" and 78 turns into the calculator. Now if you wanted to use #28 enamelled wire, you would need a space of 1.11" on the coil and the inductance would be 244.9 uH.

A "spaced" coil is one that has a gap between turns. An example is a coil that is 1 inch long and has 8 turns of #24 wire "spaced" along the 1 inch length.There is a significant gap between turns. To calculate the inductance, enter the coil diameter, the number of turns and the coil length into the calculator. The calculated inductance will appear in blue just under the entered parameters.

To Use the Resonance Calculator:

Enter the known inductance and capacitance into the calculator section at the top of the page. The resonant frequency and the reactance of the L-C circuit will be given in blue immediately below. Example: You have a 40-400pF variable capacitor and a 240uH inductor and you want to find the tuning range. Enter the inductor value, press <enter>, and the highest variable capacitor value into the calculator and press <enter>. You should see a resonance of .514 MHz. Left-click on the capacitance value and now enter 40. You should now see a resonance of 1.624 MHz. In this example would be perfect for tuning the AM broadcast band.The result is a theoretical value. The actual frequency will differ slightly due to distributed capacitance and measurement tolerances

Professor Coyle can be copied for non-commercial purposes only and is meant to be an aid in calculation. The author is not responsible for the results calculated nor any damage to equipment affected by these calculations. This program is not to be bought or sold. Please credit the author, Dan Petersen, when copying this program. Close cover before striking. Place all trays in the upright position before landing. Put the toilet seat down. Exact change only. Don't kiss the dog on the nose.

needle). Hence the secondary coil encloses a *changing* magnetic field. By Faraday's law of induction this changing magnetic flux induces an emf in the secondary coil. This effect in which changing current in one circuit induces an emf in another circuit is called ***mutual induction***.

Let the primary coil have N_1 turns and the secondary coil have N_2 turns. Assume that the same amount of magnetic flux Φ_2 from the primary coil links each turn of the secondary coil. The net flux linking the secondary coil is then $N_2\Phi_2$. This net flux is proportional to the magnetic field, which, in turn, is proportional to the current I_1 in the primary coil. Thus we can write $N_2\Phi_2 \propto I_1$. This proportionality can be turned into an equation by introducing a constant. Call this constant M, the ***mutual inductance*** of the two coils:

$$N_2\Phi_2 = MI_1 \text{ or } M = \frac{N_2\Phi_2}{I_1}$$

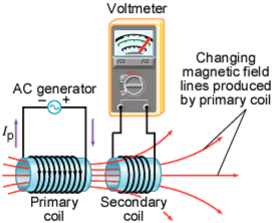
the unit of inductance is $\frac{\text{wb}}{\text{A}} = henry\ (\text{H})$ named after Joseph Henry.

The emf induced in the secondary coil may now be calculated using Faraday's law:

$$\mathcal{E}_2 = -N_2\frac{\Delta\Phi_2}{\Delta t} = -\frac{\Delta\left(N_2\Phi_2\right)}{\Delta t} = -\frac{\Delta\left(MI_1\right)}{\Delta t} = -M\frac{\Delta I_1}{\Delta t}$$

$$\boxed{\mathcal{E}_2 = -M\frac{\Delta I_1}{\Delta t}}$$

Mutual Inductance
Dr. David F. Cattell
faculty.ccp.edu/faculty/dcattell/Sp12/.../Mutual%20Inductance.doc



Suppose we hook up an AC generator to a solenoid so that the wire in the solenoid carries AC. Call this solenoid the *primary coil*. Next place a second solenoid connected to an AC voltmeter near the primary coil so that it is coaxial with the primary coil. Call this second solenoid the *secondary coil*. See the figure at the right.

The alternating current in the primary coil produces an alternating magnetic field whose lines of flux *link* the secondary coil (like thread passing through the eye of a

the critical resistance as a function of capacitance there is a problem. But the issue is most likely due to the nature of the measurement as it is difficult to tell exactly when the circuit transitions from under-damped to over-damped. Finally, the model accurately predicts the resonant frequency of a RLC circuit, however, other details of the behavior such as the Q factor are not described correctly in this experiment.

This fit is shown in Figure 10. It can be seen that this does shift the resonance from where measured (to 485 Hz) but the Q factor is the same as in the experiment. So while not entirely responsible for the difference between measurement and theory, as evidenced by the resonant frequency difference, uncounted resistances play a part in the disparity.

4 Conclusions

RLC circuit behavior is described well by oscillating system theory which describes the charge on the capacitor as a 2nd order differential equation. It is demonstrated in this experiment that the theory can be used to reliably find the inductance of a RLC loop by measuring the period of oscillation as a function of capacitance. The predicted exponential damping dependence on resistance is also verified and it is shown that that total resistance of the circuit can be found accurately using a resistance versus log decrement plot. However, when applying the theory to measure the inductance using

bandwidth of 360 − 15 Hz5. Then, using $Q = f_0/\Delta f$ it was found that the quality of the circuit was 1.4 − 0.1.

The theoretical Q is 52.8 and it is therefore quite obvious why the theoretical impedance curve is much sharper than the measured curve. The plot shows a poor agreement between the theoretical response and the actual results. The peak is much sharper for the ideal case and the bandwidth is much lower as seen in a comparison of Q values. These discrepancies are due to components not behaving ideally and other loses in the circuit such as resistance in the wires or imperfect connections on the bread board. Additionally, the actual voltage falls off faster than expected for the same reasons. Building on this idea, if we assume that the inductance and capacitance of the circuit are the same as measured and fit the function to the data by changing the resistance in equation 14, we find the best fit around R = 202 Ω.

function of frequency. We observed frequencies between 100 and 1000 Hz and set the oscilloscope to average 16 samples and measure the amplitude automatically. The results are shown in Table 6. These values are then

Table 6: Voltage versus frequency. Errors for all values are − 2 mV.

plotted along with equation 14 in Figure 9. Equation 14 is important because RM is so large that the peak to peak voltage (Vpp) should approximately equal V0Z=RM and thus is directly related Vpp. Using this plot we found the resonant frequency to be 515 − 10 Hz. Based on the measurements of the inductor, resistor, and capacitor the theoretical resonance occurs at 514 Hz which is in good agreement with our data. We also measured the bandwidth by finding the two frequencies at which Vpp fell to 70.7% of its peak value. These two frequencies were 350 − 10 Hz and 710 − 10 Hz giving a

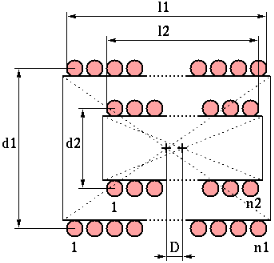
Variometer Design

Claudio Girardi
http://www.qsl.net/in3otd/variodes.html

Variometer Design

A variometer consists usually of two coaxial coils, connected in series, where the coils relative position can be varied in some way. If L1 and L2 are the self-inductances of the first and second coil and Lm is the mutual inductance between the two, the total inductance can be written as Ltot=L1+L2±2Lm. The mutual inductance is defined as the flux linked by the turns of an inductance when the other carries a unit current; this of course depends not only on the coil length and diameter but also on their relative position.
For two coaxial coils, like the ones in the picture, the mutual inductance is at maximum when they are also concentrical, i.e. D=0.

If the two concentrical coils are rotated, so that their axes are not parallel any more, the mutual inductance decreases, reaching zero (almost) when the angle is 90°. Continuing the rotation beyond 90° the mutual inductance increases again, but this time with the opposite sign. So, according to the above formula,

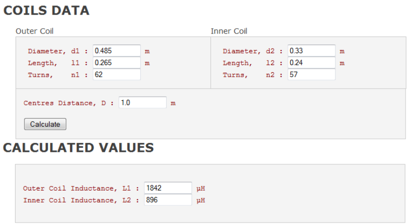


rotating a coil 180° gives a variation of the total inductance of 4Lm.

Two coaxial coils If the two coaxial coils are moved along their axis instead (D<>0), the mutual inductance decreaes, eventually reaching zero at infinity, but does not change sign. This means that there is less variation in the total inductance just moving the coils with respect to rotating them.

The form below computes the main parameters for the two types of variometer described above. The self-inductances are calculated using the formulas in [1], while the mutual inductances use the formulas from [2], with some minor corrections.

These formulas agree very well with the results of some electromagnetic simulations I have done, see the page for details.



COILS DATA

Outer Coil

Diameter, d1 : 0.485 m
Length, l1 : 0.265 m
Turns, n1 : 62

Inner Coil

Diameter, d2 : 0.33 m
Length, l2 : 0.24 m
Turns, n2 : 57

Centres Distance, D : 1.0 m

CALCULATED VALUES

Outer Coil Inductance, L1 : 1842 µH
Inner Coil Inductance, L2 : 896 µH

In a typical variometer the two coils are concentric (i.e. D=0) and the overall inductance is varied rotating the inner coil; in this case we have:

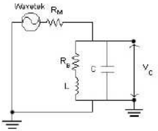


Figure 8: Circuit layout for part D

When analyzing AC circuits it is convenient to use impedances to determine various aspects of the response. For example, with this circuit, the impedance can be used to determine the magnitude of the voltage across the RLC element as

$$V_C = V_0 \frac{R}{R_M + Z} \tag{13}$$

Impedances are complex numbers in general and for a capacitor Z = 1=j!C, for an inductor Z = j!L, and for a resistor Z = R where j = p □1. As can be seen in Figure 8 the RLC loop has the capacitor in parallel with a series addition of the resistor and inductor. Using the addition rules for circuits the result is that

$$|Z| = \frac{\sqrt{R^2 + (\omega L)^2}}{\sqrt{\left(1 - \frac{\omega^2}{\omega_0^2}\right)^2 + (\omega RC)^2}} \tag{14}$$

where !0 is the resonant frequency.

With this in mind we set out to observe this response by measuring the peak to peak voltage across the capacitor as a difference and based on this it would seem all of our measurements of Rcritical were too low by at least 15%. However, when the resistance is adjusted upwards that much it is readily apparent that the circuit has moved into being over-damped based on the waveform. Therefore, it must be concluded that this is not a reliable way to measure an inductance at least partially due to the subjectivity of the measurement.

3.5 Part D: RLC response to sinusoidal signal

For this section a different circuit was used than in parts A, B, and C. The circuit is shown in Figure 8. RM was 101 k , L was 93 mH, RB was 5.69 , and C was 1.03 ┬ F. Also, the Wavetek was set to output a sine wave with an amplitude of 16 V.

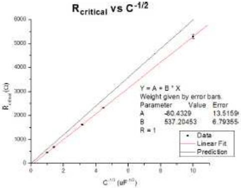

Figure 7: Plot of Rcritical versus 1/p C showing a strong linear relationship. Additionally, a plot of the theoretical behavior given the measured inductance is shown.

Mutual Inductance, M : 703 µH
Min Inductance Value, Lm : 1333 µH
Max Inductance Value, LM : 4144 µH

When the coils can not rotate but only move along their axis (coaxial coils), assuming a distance D between the two coils centres, we have:

Mutual Inductance, Md : 10.4 µH
Total Inductance, Ld : 2759 µH

The total inductance value for this case is computed assuming a positive mutual inductance (coils not rotated 180°).

Figure 6: Sample circuit response for this part of the experiment

Table 5: Rcritical versus capacitance.

C (μF)	$R_{critical}$ (Ω)
1	460 ± 10
0.5	678 ± 10
0.1	1620 ± 30
0.05	2320 ± 30
0.01	5300 ± 100

the error values a change in the response was observed that we believe was significant enough to warrant a high degree of confidence (assumed to be 95%) in that range.

A plot of these critical resistances versus 1/p C is shown in Figure 7. Additionally, the ideal behavior is plotted using L = 90 mH. The first result to notice is that the linear fit is very strong and that the error in the slope is only 2.3% with 95% confidence. However, it is also clear that the plot implies a different value for the inductance of the circuit than previously found. Based on the slope of the fit, the inductance of the circuit is 72 − 3 mH with 95% confidence4. This gives a 20%

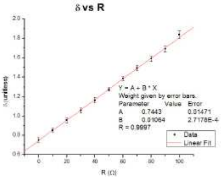

Figure 5: Graph of versus R showing a good fit and match to theory.

3.4 Part C: Dependence of resistance for critical damping on capacitance

For this part of the experiment the same circuit and waveform is used as in part B. The critical resistance is the resistance at which the circuit is critically damped. Therefore b2 = 0 and by solving equation 3 we find

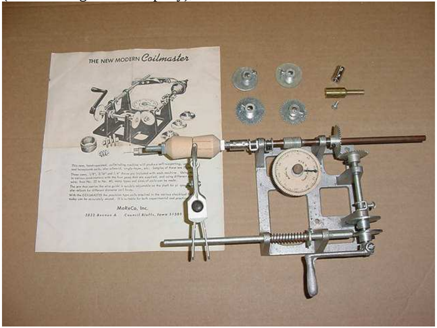
$$R_{critical} = 2\sqrt{\frac{L}{C}} \qquad (12)$$

So a plot of R vs 1/p C should be linear. We determined the critical resistance by adjusting the decade resistance box and observing the resulting waveform. Three example waveforms are shown in Figure 6. To find where the circuit was critically damped we allowed it to be slightly under-damped and then increased the resistance until no overshoot was observed. We did this for 5 different capacitances and our results are summarized in Table 5. Unfortunately we did not have one definitive way to determine the error in our measurement. However, when the resistances were adjusted by 7

Get/Make a "Coilmaster"
http://www.qsl.net/k5bcq/COIL/COIL.html

Get/Make a "Coilmaster"

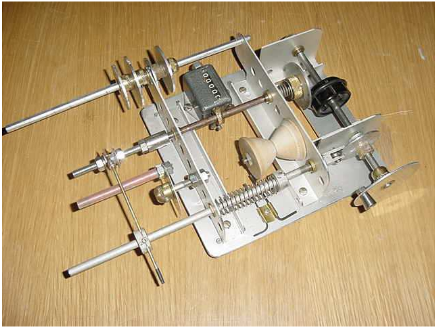
This is "The New Modern Coilmaster" made by MoReCo (MOrris REgister COmpany), Inc. of Council Bluffs, Iowa.



If you want to wind your own coils, and many people did, you need to build one of these. They are really pretty simple as you can see and with a little ingenuity you can make one. The turns counter is driven off a worm gear. The spring in front is to maintain contact between the wire guide assy and the different shaped cams, moving it back and forth. The cam is mounted right behind the crank handle. Each Coilmaster is equipped with four 32 pitch gears, with 39, 40, 42, and 44 teeth. This would give it a spindle to cam ratio of approximately 0.9:1 to

1.1:1. It says enameled wire must first be treated to give it "grip" by passing it through a quick-drying solution, such as resin dissolved in alcohol or other similiar material. Had you guessing too, huh ? Extra cams were $0.75 and gears were $1.00.

A Homebrew "Coilmaster"



This is homebrew "Coilmaster" using "whatever is available" parts. It has a variable spindle to cam ratio from 0.9:1 to 2.1:1, various cams, various wire feed heads, wire spool holder, turns counter, etc......even comes with two allen wrenches. It is shown with a small plastic bobbin coil spool mounted. Additional cams are located on the wire spool holder shaft and also prevent the wire feed spool from coming too close. The wooden spools are mounted on the spindle for large inner diameter coils.

$$\delta = \left(\frac{R}{2L}\right)\frac{2\pi}{\sqrt{\frac{1}{LC}-\left(\frac{R}{2L}\right)^2}} = \pi\frac{R}{L}\sqrt{LC}\frac{1}{\sqrt{1-\frac{R^2C}{4L}}} \approx \pi\sqrt{\frac{C}{L}}R$$

(11)

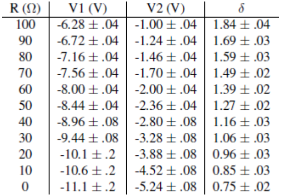
when R2C=4L 1. In this experiment, the maximum value of R2C=4L is 0.08 and can fairly safely be ignored to test for linearity. Figure 5 shows versus R and a strong linear relationship is observed. Based on the fitting parameters the x intercept of the line is not R = 0

. This is because R is referring only to the resistance of the decade box and ignores the resistance of the coil and the function generator output. This residual resistance is calculated to be 70 − 4

with 95% confidence. The combined resistance of the inductor coil with the stated output resistance of the Wavetek is 69.4

giving a good agreement with the above measurement.

Table 4: versus resistance.



R (Ω)	V1 (V)	V2 (V)	δ
100	-6.28 ± .04	-1.00 ± .04	1.84 ± .04
90	-6.72 ± .04	-1.24 ± .04	1.69 ± .03
80	-7.16 ± .04	-1.46 ± .04	1.59 ± .03

0	-11.1 ± .2	-5.24 ± .08	0.75 ± .02

Table 3 with the errors in voltage determined by multiplying the minimum change by 2.3 The error becomes worse as the peak number increases

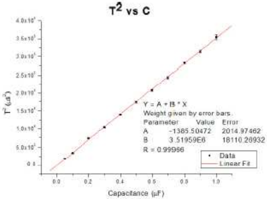

Figure 4: Plot of T2 versus C showing a straight line as predicted by theory.

Table 3: Verification of constant

Peak #	Voltage (V)	δ
1	$7.48 \pm .04$	N/A
2	$3.44 \pm .04$	0.78 ± 0.01
3	$1.56 \pm .04$	0.79 ± 0.03
4	$0.76 \pm .04$	0.72 ± 0.06

because the data was only acquired once with a set vertical resolution on the scope, and thus the uncertainty as a percentage of the value increased as well.

With the consistency of established we proceeded to measure as a function of R. The first and second peaks were measured and used to determine . This data appears in Table 4. Again the error was determined by multiplying the smallest change in V on the scope by 2. Plugging equations 2 and 4 to equation 5 gives

---

The whole thing is made from aluminum scrap. Since aluminum is soft (and easy to work), the wear points are strengthened with brass bushings from old potentiometers. Be sure to grease all the bearing surfaces or they will jam. All shafts are 1/4" (steel or aluminum) cut to size. The collars are made from old knob inserts after the plastic/bakelite is removed via an application of cold chisel. The cams are made from knobs with thick aluminum skirts (plastic/bakelite removed). Some required a little hammer tweaking to tighten the skirt. Since the cam is soft it rides on a small ball bearing (from an old PC disk drive) cam follower.

The drive "gear" is a knob with a groove cut into it. A small "O" ring is installed into the groove and contacts/drives the aluminum skirt of another knob. A short spring is located behind the skirted knob to insure pressure on the "O" ring. Ran into one problem on my coil winder. The "O" ring kept "walking" off the knob on the right angle drive. After a little study, I decided that the "O" ring footprint is not "zero", so the inside of the track is actually running at a different ratio than the outside of the track. This tends to cause an outward force on the "O" ring in the plane of the "O" ring drive shaft. If the centerline of the "O" ring drive shaft is below that of the driven plate shaft centerline, you also have the additional outward force due to the direction of rotation of the driven plate. The way I solved the problem is to equalize the forces by locating the "O" ring drive shaft centerline ABOVE the center line of the driven plate (for this size plate, "O" ring, etc it turns out that 3/32"-1/8" works best). No more problem, everything runs true at any ratio. This was the first Engineering Change to my coil winder .....the driving shaft bushings are now mounted in vertical slots.

The crank is yet another aluminum skirted knob. The mechanical counter was something from a swapmeet and lends itself to being worked with a beveled collar. I could have used a cam to work the counter, but the counter reset knob would have been difficult to get to. The wire feed is a small hobby shop brass tube run through a drilled knob insert with one set screw used to hold the tube in place and the other used to tighten it to the shaft. This tube easily feeds #24 AWG and smaller wire but a larger tube could be used and you can make several wire feed heads. Most coils I need will be #28 AWG or smaller. It has a bail made from a safety pin on the end. The wire is fed into the back of the tube and wire tension is controlled with your fingers. A small piece of shrink tubing was put on the end to further protect the wire. The wire feed head rests on an adjustable bar to control height (yet another knob with aluminum skirt). Fun project.

The additional holes in the braces are for better cooling and to decrease weight ...Hi, Hi.

......and we have the "Cheapo-Winder"

95% confidence1. Based on this value for the inductance it is determined that for C = 1 uF and R = 70 Ω.

$$\left(\frac{1}{LC}\right) = 1.11x10^7 \gg 1.51x10^5 = \left(\frac{R}{2L}\right)^2 \tag{9}$$

and therefore, according to equation 4

$$T^2 \approx (2\pi)^2 LC \tag{10}$$

This relationship is plotted in Figure 42. Again, the R value shows a strong linear relationship between the values as predicted and the error in the slope is only 0.9% with a 95% confidence interval.

Finally, the inductance of the coil was measured using a Z-meter and found to be 92− 1 mH. This is in good agreement with the value determined from the 1/T2 versus 1/C relationship.

3.3 Part B: Log decrement dependence on resistance

For this section of the experiment the same circuit and waveform was used as in part A. The capacitance was set to 1 ┬ F. First we observed the voltage transient at R = 0, 50, 100, 150, 200, 250, and 300 . Above 100 it became difficult to see more than 2 oscillations. Next we verified that the log decrement ( ) did not change going from one set of peaks to the next. We did this by setting the resistance to 0
and measuring the height of the first 4 peaks allowing 3 successive s to be calculated. The results are summarized in

value. Then the error of the single period was just the error of the total time divided by the numer of periods for that measurement. According to equation 4 a plot of 1/T2 versus 1/C should give a straight line with a

$$m = \frac{1}{4\pi^2 L} \tag{7}$$

Figure 3 shows this relationship along with the best fit line. The error bars were calculated using the propagation of errors formula:

$$Error = \sqrt{\frac{4}{T^6} T^2_{error}} \tag{8}$$

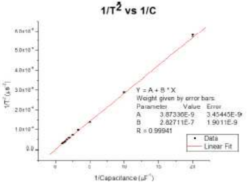

Figure 3: Plot of 1/T2 versus 1/C showing a straight line as predicted by theory.

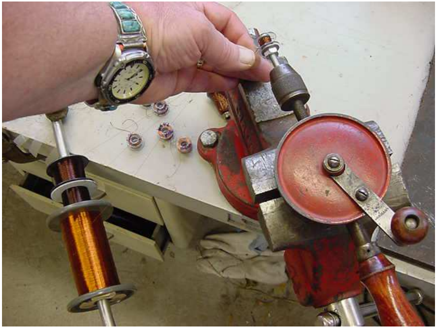
In this plot the 'Error' column refers to the standard error and it can be seen that the R value indicates a strong linear relationship. Using the relationship in equation 7 it was determined that the inductance of the circuit was 90− 1 mH to



This is "The Old Cheap Econo-Winder" used by many, including myself. It offers the advantages of: no cams to change, no gears to change, 4x chuck to crank ratio, infinitely adjustable, full control, able to wind multiple strands (above photo shows three #38 AWG strands being fed onto a spool). You are the turns counter....multiply the drill crank turns by 4.3 (this drill gear ratio). Turn the crank with one hand, tension and feed the wire in a pattern with the other hand. If you can "pat your head with one hand and rub your belly with the other", you can wind coils by hand. I you can't ....see above.

A few winding hints/ideas/observations

Your results will probably vary some from mine, but the general ideas will hold.

* It was pointed out to me that the main advantage of a winding machine is to allow a "basket weave" pattern which reduces adjacent turn/layer capacitance and increases coil "Q". Basket weave also tends to stay in place better than level wound coils because it's a diagonal criss-cross ....and it looks cool. You can manually wind a very acceptable "basket weave" pattern by hand with a hand drill or with a coil winder. It doesn't have to be "exactly correct" to see the advantage of higher coil "Q". Hand winding will generally require a spool or something to keep the end turns from collapsing. Coil winder made coils can be wound "free standing" if they are not too tall and you use a 2:1 spindle to cam ratio (my opinion).

* Using Litz wire or multi strand (individually insulated) wire increases the surface area which reduces resistance at RF frequencies due to "skin effect" (concentrates the RF current on the outer surface of the wire) and increases coil "Q". Litz wire is useable at frequencies of 2-3Mhz or LOWER. Above 2-3Mhz, solid wire performs as well as the Litz (from Therman's book). The manufacturers of Litz wire twist and alternately place the conductors relative to each other to reduce eddy currents, capacitance, keep impedance constant, etc. The inductance of one strand is about that of two strands, is about that of the whole bundle for Litz wire ....even though the "individual" coil inductances are, in effect, "paralleled". This is because of the close coupling of the wires.

* When winding with served Litz wire, you will find that it lays down easily and makes nice coils. Solid wire (single or multistrand) will also lay down easily if you feed it across a block of beeswax to give it "stick". You will find that the Litz wire does have higher "Q" but it's "bulkier" than the equivalent solid wire (will take up more space). Litz wire will have a tendency to kink as it comes off the spool due to the wire twist.

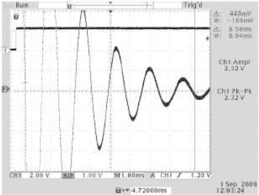


Figure 2: Representative transient signal of voltage across capacitor in this part of the experiment.

used. This was done for 11 different capacitances over the range of 0.05-1 μF. The results are shown in Table 2. The error for the total time was taken to be the resolution of horizontal axis of the Tektronix multiplied by 2. We assumed that this large range gives a 95% confidence in the

Table 2: Measurement of period of oscillation as a function of capacitance.

C (μF)	# of periods	Total time (ms)	Single period (ms)
1	5	9.40±.08	1.88±.02
0.9	5	8.86±.04	1.77±.01

0.3	7	7.14±.04	1.02±.01
0.2	9	7.70±.04	0.856±.004
0.1	13	7.64±.04	0.588±.004
0.05	9	3.75±.02	0.417±.002

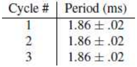
with serial number Phys-943034 was used to measure the resistance of the inductor coil #7. A Wavetek function generator was used in all parts and had the serial number Phys-943026. Additionally a Tektronix TDS3012B oscilloscope with serial number F28819 was used to measure the transient response in all parts.

3.2 Part A: Frequency dependence on capacitance

In this section, along with parts B and C, the Wavetek and circuit were connected as shown in Figure 1. VC was measured using the Tektronix scope and Rout was assumed to be 50 . R in the figure was a decade resistance box and C was a decade capacitance box. L was a large coil inductor (#7) which we measured the resistance of using the DMM before turning on the Wavetek. The resistance was found to be 19.36 . The Wavetek was set to output a 8 V unipolar square waveform with a frequency of 10 Hz and a duty cycle of 50%. The oscilloscope was set to trigger on the leading edge of the unipolar output of the Wavetek.

After all the elements had been setup, the resistance box was set to 0 and it was verified that the period was constant for each oscillation as shown in Table 1. Additionally a representative scope output is shown in Figure 2.

Table 1: Verification of constant period.



Cycle #	Period (ms)
1	1.86 ± .02
2	1.86 ± .02
3	1.86 ± .02

Then we measured the period of oscillation for different capacitances by determining the time to complete multiple cycles and dividing the result by the number of cycles

---

* To measure the capacitance between conductors of bifilar or Litz wire, measure only a foot or so of wire and extrapolate to the total length (via resistance measurements). If you measure the capacitance on the spool, you will see a very small (in error) reading. The reason is that you are trying to measure capacitance across two really good RF chokes with a tester which uses an RF frequency to determine capacitance.

* Litz wire is sometimes a little confusing. For example: 6/44 unserved Litz wire means 6 strands of #44 AWG wire without an overall wrap (unserved). The AWG "equivalent circular mills" for 6/44 Litz is #36 AWG. This means that 6/44 Litz has the same circular mills and DC current handling capability as one #36 AWG wire. However, the RF current resistance of 6/44 Litz is less than half that of the #36 AWG wire and approaches that of #28 AWG wire. What all this means for the coil is that 6/44 Litz will have a higher "Q" than the equivalent solid wire of equal DC current capability (#36 AWG), but it will take up more space. Unserved 6/44 takes up the space of #34 AWG and served 6/44 takes up the space of #32 AWG.

* From what I've seen, manufacturers of small IF transformers in the 100Khz to 455Khz range use single #38 AWG wire (good), bifilar #40-42 AWG wire (better) or trifilar #44 AWG wire (best) for the windings (allows 18-28ma DC). The smaller JW Miller 100Khz IFs also have a ruberized "powdered iron?" layer inside the aluminum can. I believe the reasons for this layer is to further increase permeability and to isolate the coil from the can. The fact that 100Khz IFs require 5-6mH of inductance dictates a physically large coil, the large coil results in increased capacitive coupling to the can, which reduces "Q" and overall inductance. The higher permeability and resultant higher "AL" value (uH/100turns) is needed to keep the overall coil size manageable in the smaller 3/4" square IF shields.

* Spindle to cam shaft ratios for small IF type coils seem the be 2:1. This means the wire feed head traverses from one side to the other in one spindle revolution and traverses back during the second spindle revolution. I don't think a Morris "Coilmaster" can do that. A 1:1 spindle to cam shaft ratio means the wire feed head traverses to one side and back during one spindle revolution.

* Tuning slug/cup material permeability can vary substantially (just like toroids) and Amidon lists permeabilities up to 35 for their slug tuned coil forms. The 0.01 to 0.50Mhz "3" material has a permeability of 35. As an example: one 455Khz IF (which you would expect to have a high permeability slug) measures 0.7mH without a slug, 1.5mH (max) with it's powdered iron slug and 2.5mH (max) with another powdered iron slug from a JW Miller 100Khz IF (obviously with a higher permeability). Some of the physically small coils, like those in 3/8" cans use very high permeability ferrite cups to reduce coil size requirements.

* When swapping tuning slugs for one you just had to drill out because it broke, make sure the permeabilities are about the same or it won't tune correctly. Could never get that Heathkit HF osc to peak....huh ?.

* One source of low frequency, high permeability slugs is old TV horizontal osc coils. If you need to shorten a powdered iron slug, scribe it with a hacksaw and snap it by hand. A simple method for determining relative permeability is to swap slugs in a given coil form and measure the inductance.

* Coil spools solve the problem of the end turns "collapsing" on small coils, especially if you are not using a coil winder. The coil spools used are plastic "Singer" Class 15 (11/32" tall winding) or "PFAFF" (7/32" tall winding) sewing machine bobbins available at any sewing store (or the wife's sewing room ....but be careful, they don't share your enthusiasm). Coil winding using the wife's sewing machine "bobbin winder"

$$\delta = \ln \frac{q(t_{max})}{q(t_{max} + T_1)} = aT_1 \qquad (5)$$

The last equality in equation 5 can be made based on the form of q(t) where e^{-at} is the attenuating factor. Lastly, the quality factor Q of the circuit is defined as

$$Q = 2\pi \frac{total\ stored\ energy}{decrease\ in\ energy\ per\ period} = \frac{\pi}{\delta} = \frac{\omega_1 L}{R}$$

(6)

with $\omega_1 = 2\pi f_1$ being the damped angular frequency. As can be seen, a lower resistance leads to a higher quality while a higher inductance increases Q.

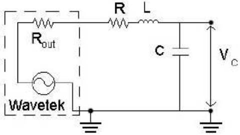


Figure 1: Circuit layout for parts A, B, and C.

3 Experiment

3.1 Equipment

A decade capacitor and decade resistor were used in parts A-C. The serial number for the capacitor was A-1678 and for the resistor was 48288. A HP 34401A Digital Multimeter (DMM)

$$b = \sqrt{\left(\frac{R}{2L}\right)^2 - \left(\frac{1}{LC}\right)} \tag{3}$$

There are three distinct types of solutions depending on whether b2 is positive, negative or zero.

When b2 = 0 the circuit is said to be critically damped. In this case the two roots of the characteristic equation are real and the same value. Therefore, the charge in the capacitor falls to zero exponentially and quicker than for any other value of b.

When b2 > 0 the two roots of the characteristic equation are real and again the charge drops to zero in an exponential fashion. However, the falloff of charge is slower than for b2 = 0. This can be seen by observing that at later times the decay constant is (a □ b) < a. With this type of response the circuit is said to be over-damped.

Finally, when b2 < 0 the two roots are imaginary and thus the charge oscillates about 0 before finally decaying to 0 (assuming a 6= 0). Under these conditions the circuit is said to be under-damped. The frequency of the oscillation is

$$f_1 = \frac{1}{T_1} = \left(\frac{1}{2\pi}\right)\sqrt{\left(\frac{1}{LC}\right) - \left(\frac{R}{2L}\right)^2} \tag{4}$$

where T1 is the period of the oscillation. Because the charge is still decaying the logarithmic decrement δ can be defined as the natural log of the ratio between two successive peaks of charge

does not work and can shorten your life. A "Singer" Class 15 or "PFAFF" bobbin has a thicker core and lends itself to being drilled out to 19/64", 9/32", or 17/64" which allows them to be put onto standard 1/4" slug tuned cores. Trim the spool with wire nippers and since it's an outside curved edge, a finger nail clipper works well. Trim the spools after you have wound them to keep the newly created rough edge from cutting small gauge wire or smooth the spool edge before winding. If the spools are not the correct height, cut them in half or make some "washers". It's important to secure these solidly to the coil form or the winding will tend to "walk" the washer ends outward. When done, carefully remove the washers and add some beeswax/Q dope to seal the outer turns.

* To keep the initial turns from slipping add a layer of double sided tape to the core or drip some beeswax onto the core (preferred).

* Many types of magnet wire allow direct tinning of the wire which burns off the insulation in the process. This is MUCH easier than scraping the insulation off with a razor blade, especially for the smaller gauges. Burning off the insulation over a flame is not advised.

* Aspect ratio is important. A fixed length of wire was wound on a given form and slug. The coil winding height on one was 3/8" and 3/16" on the other. The 3/16" winding (larger outer diameter) measured 40% (max) more inductance. Therman says optimum inductance is achieved if the winding cross section is square. Slug tuned coils may be different.

* To give the wire more "stick" as you are winding, feed it across and into a beeswax block (available at art/craft and sewing stores).

Factors Affecting Coil Q ...some experiments

EXPERIMENT #1 ....Skin Effect

Four coils were wound by hand. Coil Q will increase if the turn-to-turn capacitance is reduced. This can be accomplished by using a "basket weave" pattern. The "basket weave" coils have roughly 1-2 spool length traverses of the wire per revolution of the spool (coil Q will be even higher on fixed pattern wound coils made using a coil winder). Q can also be increased by using multi strands of smaller gauge wire due to increased surface area (skin effect) at frequencies below about 3Mhz. It's a substantial improvement in Q to use two strands of #39 AWG vs one strand of #36 AWG, or better yet .....six strands of #42 AWG vs one strand of #36 AWG. All three of those examples have the same current handling capability. Many small, higher quality, IF transformers are wound with two strands of smaller gauge wire. Larger, high quality IF transformers are wound with Litz wire, dipped, etc.

All coils were trimmed to 2.0 mH with no slug, and 3.0 mH with a slug. Q Data is "unloaded Q" as measured on a Boonton 260-A.

At 200Khz, all coils trimmed to 2mH, no tuning slug

Coil #1 #34 AWG, level wound, 325pf, Q of 52
Coil #2 #34 AWG, basket weave wound, 320pf, Q of 55
Coil #3 two #38 AWG, basket weave, 310pf, Q of 78
Coil #4 three #38 AWG, basket weave, 320pf, Q of 83

At 170Khz, all coils trimmed to 2mH, no tuning slug

Coil #1 #34 AWG, level wound, 440pf, Q of 55
Coil #2 #34 AWG, basket weave wound, 447pf, Q of 57
Coil #3 two #38 AWG, basket weave, 433pf, Q of 78

RLC loop when an external voltage was applied. The capacitance was varied and the periods of the oscillations were used to determine the inductance in the circuit. Next we measured the log decrement as a function of resistance to verify the response is approximately linear and to estimate the total resistance of the circuit including the inductor and the function generator. Following that we determined the resistance required for critical damping as a function of capacitance. Using this we verified the theoretical result that the critical resistance is proportional to 1/ p C. Finally, we measured the voltage across the capacitor in a different RLC circuit driven by a sinusoidally varying voltage. The peak-to-peak voltage was measured as a function 1 of frequency to determine the resonant frequency, the bandwidth, and the quality factor Q. We also compared the resonant frequency with the theoretical value.

2 Theory

The governing equation for a resistor, inductor and capacitor in series with a voltage source is

$$L\frac{d^2q}{dt^2} + R\frac{dq}{dt} + \frac{q}{C} = V(t) \qquad (1)$$

This is the equation for an oscillator with damping and a driving function. Solving the characteristic equation gives two roots s1; s2 = a − b with

$$a = \frac{R}{2L} \qquad (2)$$

Transients and Oscillations in RLC Circuits

Will Chemelewski with Brian Enders

http://courses.physics.illinois.edu/phys401/Files/Misc/Sample%20report%20RLC.pdf

Abstract

Transient responses of RLC circuits are examined when subjected to both long time scale (relative to the decay time) square wave voltages and sinusoidally varying voltages over a range of frequencies about the resonant frequency. In general, a good correspondence is found between theory - describing the charge in the system in terms of a 2nd order differential equation with a harmonic oscillator form - and experiment. It is demonstrated that the inductance can be accurately measured using period of oscillation versus capacitance measurements. Furthermore, the exponential decay of the response is described well by the model and the resonant frequency of a sinusoidal external voltage is accurately predicted. However, some discrepancies were found though not necessarily a result of theoretical failures. One problem is the failure to predict the inductance of a circuit based on the critical resistance variation with capacitance, although the problem could lie in how the measurement is conducted. Additionally, the quality and bandwidth of a RLC element is poorly predicted but this could also be a result of experimental problems.

1 Purpose

The purpose of this experiment was to observe and measure the transient response of RLC circuits to external voltages. We measured the time varying voltage across the capacitor in a

Coil #4 three #38 AWG, basket weave, 446pf, Q of 85

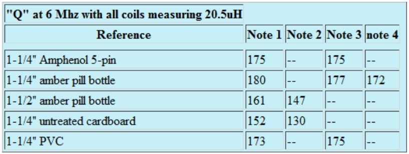
At 150Khz, all coils adjusted to 3mH with the tuning slug

Coil #1 #34 AWG, level wound, 400pf, Q of 82
Coil #2 #34 AWG, basket weave wound, 380pf, Q of 85
Coil #3 two #38 AWG, basket weave, 380pf, Q of 109
Coil #4 three #38 AWG, basket weave, 385pf, Q of 114

EXPERIMENT #2 ....Coil Form Dielectrics

Other factors which effect coil Q are the coil form material and the adhesive used to hold the windings. Any coil form which can absorb moisture, like the old cardboard oatmeal boxes and toilet paper tubes used for crystal sets, is a problem unless the cardboard is treated with varnish, shellac, etc ....but it's cheap.

Some have suggested using old plastic pill bottles which is OK if they are sturdy so the coil turns don't move. Recently some testing has shown that coils wound on those amber pill bottles have just has high a "Q" as those wound on the Amphenol 5-pin forms. Some PVC is the same way. What does affect "Q" is the material you use to coat the windings (materials to be tested later ...beeswax, refined paraffin, varnish, laquer, other "glues"). Here is an example of coils wound (adjacent turns) with #28 AWG magnet wire:



"Q" at 6 Mhz with all coils measuring 20.5uH

Reference	Note 1	Note 2	Note 3	note 4
1-1/4" Amphenol 5-pin	175	--	175	--
1-1/4" amber pill bottle	180	--	177	172
1-1/2" amber pill bottle	161	147	--	--
1-1/4" untreated cardboard	152	130	--	--
1-1/4" PVC	173	--	175	--

Notes:

Plain wiring, no adhesives, no tape to hold windings

Use a light coat of clear fingernail polish to hold windings (strips across windings didn't work), Q reading 15-20 points lower when first applied, above readings are after 48 hours.

Use Elmer's Stix-All silicone to hold windings (4 strips across coil windings)

Use Scotch black electrical tape to hold coil windings (1-1/2 turn)

EXPERIMENT #3 ...Turn Spacing

The highest Q coil for a given inductance is "air wound" with space between the turns (less turn-to-turn capacitance), the next is space winding on a good coil form (ceramic, phenolic, etc). Space winding on a coil form by winding string or another wire along with the coil wire and removing the "spacer" later is good. Ceramic and some phenolic coil forms came with wire groves to space the turns. You do have the problem of having to stabilize the separated turns with Q-Dope, paraffin, Duco cement, etc.

Here is some data on two coils:

---

stripped. You will be left with nice clean varnish-free wires, which can then be tinned as usual.

As a test of this method I measured the AC impedance of each of the wires of the same length at 10kHz using my LCR meter, and found that they all were very consistent, indicating that I was effectively and consistently removing the varnish and using all the wires in the bundle.

By the way, the speakers sound terrific! I'm not sure how much of the improvement was from the litz wire, but it certainly didn't hurt the sound!

found it works, but you end up oxidizing the wires and even incinerating some of the smaller strands),

5) Individually sanding each strand (I'd be doing this job for years as each wire has dozens of strands and I have 6 tweeters, 6 midranges and 4 woofers to wire up to 18 capacitors and 20 inductors!).

I tried several of these methods, and none were satisfactory in producing a nice clean tinned wire end, without breaking or damaging the strands. However, I did eventually come up with a simple, fast and very effective method, so I thought I would share it with the other DIY'ers here, in case they are crazy enough to build something with litz wire.

A Dremel tool with a stainless steel wire wheel attachment works very well. I found that the stainless wheel works faster and lasts longer than the carbon steel wheel, with the added advantage that the small pieces of the wheel brush that wear off during the process are non-magnetic, so they won't attach to nearby driver magnets (don't need little pieces of wire inside my EMIMs and EMITs!). Simply remove ~ 1/2" of the insulation, then untwist the various strands from each other (the Cardas Litz has 3 counterwound layers of different diameter wire to untwist, do them one at a time) and flatten them into a flat fan shape. Set the Dremel to about 1/2 of maximum speed and apply to the coated wire, ensuring that the wheel is ALWAYS turning toward the ends of the wire (otherwise they will entangle with the spinning wire wheel and snap off!). 10 seconds on each side of the fanned wire is very effective at removing the varnish coating without destroying the wires. Then re-fan the wire in a different direction and repeat the process 2 or 3 times to ensure that all the wires get

1-1/4" coil form (amber pill bottle)
both coils 13.8uH +/- 0.1uH
both coils #28 AWG wire
coil "A" 16 turns are adjacent
coil "B" 20 turns are on .025" centers +/- (spacer was removed)
both coils, no adhesives/coatings to hold the turns in place

At 3.4MHz ..... coil "A" Q=107, coil "B" Q=175

Granted, these are unloaded Q measurements on a Boonton 260-A and loaded Q will be less, however the improvement will be carried over and the "trend" is there.

What does this mean for the signal (loaded Q will be less dramatic):

Sensitivity ...the Boonton uses a 20mVAC "e" signal and measures "E" with a very sensitive voltmeter, so a Q of "107" means "E" is 2.14VAC ....a Q of "175" Q means "E" is 3.5VAC ....higher sensitivity.

Selectivity ....Q is also the -3db voltage BW divided into the frequency (Q = Fo/-3dbBW ...or -3dbBW = Fo/Q). For a Q of "107" the -3dbBW is 31.8Khz. For a Q of "175" the -3dbBW is 19.4Khz .....better selectivity.

EXPERIMENT #4 ....Coil Dope

"E6000" Craft Glue was used on a coil with a Q of "175" ...absolutely no change in Q as you put the material on, as it dries, or 24 hrs later, even for a very heavy application of glue. I believe it's some kind of silicone based product .....waterproof, clear, and remains flexible. My wife didn't even tell me she had some "really good coil dope" material in her crafts pile.

"CG Clear Ice" fingernail polish was used on a coil with a Q of "107" and the Q dropped to "97".

Considering the amplitudes of successive cycles when cos(ω dt- ϕ) = 1

$$x_n = X_0\, e^{-\zeta\omega_n t_n} \quad \text{and} \quad x_{n+1} = X_0\, e^{-\zeta\omega_n(t_n + T_d)}$$

$$\text{Therefore} \quad \frac{x_n}{x_{n+1}} = e^{\zeta\omega_n T_d}$$

The logarithmic decrement δ is ln(xn / xn+1).. Normally n =1 and n+1 is therefore 2.

$$\delta = \ln\left(\frac{x_n}{x_{n+1}}\right) = \zeta\omega_n T_d = \zeta\omega_n \frac{2\pi}{\omega_d} = \zeta\omega_n \frac{2\pi}{\omega_n\sqrt{1-\zeta^2}}$$

The damping ratio ζ can be expressed in terms of the logarithmic decrement δ as follows

$$\zeta = \frac{\delta}{\sqrt{(2\pi)^2 + \delta^2}}$$

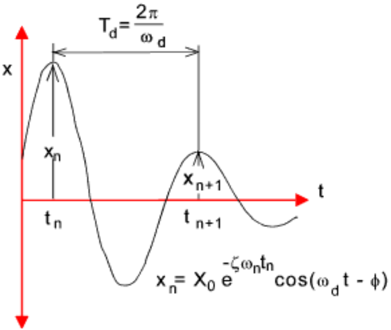
It is clearly possible to determine the damping ratio experimentally for a mechanical system be initiating vibrations and measuring the amplitude of the vibrations.

Logarithmic Decrement....

Roy Beardmore 17/01/2013

http://www.roymech.co.uk/Useful_Tables/Vibrations/Free_Vibrations.html

The rate at which the amplitude of vibrations decays over time provides a very useful method of identifying the degree of damping. See the figure below for the plot of a typical underdamped vibration.



The equation for of motion for underdamped oscillations arrived at above can be used to establish the amplitude of any of the cycles. i.e.

$$x_n = X_0 e^{-\zeta\omega_n t_n} \cos(\omega_d t - \phi)$$

Understanding LC Tank Q, Impedance, and Losses

David Wagner

http://wiki.waggy.org/dokuwiki/crystal_radio/tank

A resonant inductor-capacitor (LC) tank is the beating heart of a crystal radio, filtering the signal of interest from the sea of radiofrequency (RF) energy received by an antenna. Properly loaded, a high-quality (high-Q) tank will give a crystal radio greater sensitivity and selectivity.

For a parallel tank, a smaller inductor and larger capacitor can result in higher Q.

$$Q=\omega R_p C = \frac{R_p}{X} = \frac{R_p}{\omega L}$$ 1)

Tank Impedance

When tuned to the station of interest, the crystal radio's LC tuning tank between the antenna and detector presents a very high resistive impedance *to ground*. Estimating the magnitude of this effective shunt resistance is not difficult, but it is important to keep in mind how the tank impedance is in parallel with both the source and the detector/load impedance.

If the source and load impedances are low in comparison to the tank's shunt resistance, this resistance may be neglected, the tank loss will be fairly low, and the antenna can be matched directly to the serial combination of the detector and the audio load. However, passing a low impedance signal significantly loads the tank and results in broader tuning. To minimize tank loading, the signal impedance will approach the tank's shunt resistance, and this resistance must be considered as part of the driven load. Estimating the parallel LC tank's effective shunt resistance can be done by measuring or assuming the tank's unloaded Q.

$$R_{tank}=2\pi f\ L_{tank}Q_{unloaded}$$

Tank Loading

For efficient energy transfer, the antenna impedance should be matched to the parallel combination of the load and shunt impedances. In effect, the tank must be kept fully 'powered up' to maintain its narrow frequency response while reflecting the rest of the signal into the load.

$$R_{src}=\frac{1}{\frac{1}{R_{load}}+\frac{1}{R_{tank}}}\quad\Rightarrow\quad\frac{1}{R_{load}}+\frac{1}{R_{tank}}=\frac{1}{R_{src}}$$

The LC tank shunt resistance can then be used to estimate upper limits on the tank's loaded Q and the matched source and load impedances.

$$R_P=\frac{1}{\frac{1}{R_{src}}+\frac{1}{R_{load}}+\frac{1}{R_{tank}}}=\frac{1}{\frac{1}{R_{src}}+\frac{1}{R_{src}}}=\frac{1}{2}R_{src}$$

$$Q_{loaded}=\frac{R_P}{2\pi f\ L_{tank}}=\frac{R_{src}}{4\pi f\ L_{tank}}$$

$$R_{src}=2R_P$$

This is for very small signals.

oscillation of IL relative to the oscillation of I changes by about 180 deg. Increasing the value of the Q-factor makes this variation of phase more abrupt. However, the most important feature of the steady state solution described by Equations (19-21) is that one can reduces the frequency width of the peak in the amplitude of IL, increases its height, and chooses its frequency position, by an appropriate choice of L, r and C. That the enhancement can be made to occur in a selected, narrow frequency band by tuning the parameters of a resonant circuit is particularly useful in applications, as this makes it possible to isolate a signal occurring at a particular frequency (e.g., the emission from a radio station) from an irrelevant background.

6. To conclude

More details on LR and series LRC circuits can be found in Young and Freedman [1], chapters 30 and 31. The Physics and Maths of LRC circuits will also be studied in the Level 2 Electronics course, amongst many other things.

References

[1] H. D. Young and R. A. Freedman, University Physics, 13th Ed., Pearson Addison-Wesley, San Francisco (2012).

$$R_{load} = R_{det} + R_{audio} = 2R_{det}$$

This may not be correct since R_load(RF) may be only about half of R_load(audio) and R_load(DC).

Assume all loss is through the LC tank shunt resistance (R_tank); losses due to circulating current resistance are small in comparison to primarily capacitive losses to ground.

$$R_{src} = \frac{1}{\frac{1}{2R_{det}} + \frac{1}{R_{tank}}}$$

$$\Rightarrow R_p = \frac{1}{2} R_{src} = \frac{1}{\frac{1}{R_{det}} + \frac{2}{R_{tank}}}$$

$$\Rightarrow Q_{loaded} = \frac{1}{\left(\frac{2\pi f\, L_{tank}}{R_{det}} + \frac{2}{Q_{unloaded}}\right)} =$$

$$\frac{Q_{unloaded} R_{det}}{2\pi f\, L_{tank} Q_{unloaded} + 2R_{det}}$$ 2)

$$\Rightarrow Q_{loaded} = \frac{1}{\left(\frac{4\pi f\, L_{tank}}{R_{load}} + \frac{2}{Q_{unloaded}}\right)} =$$

$$\frac{Q_{unloaded} R_{load}}{4\pi f\ L_{tank} Q_{unloaded} + 2R_{load}}$$

The tank loss can now be estimated.

Efficiency (%): $\frac{R_{tank}}{R_{tank} + 2R_{det}} = \frac{\pi f\ L_{tank} Q_{unloaded}}{\pi f\ L_{tank} Q_{unloaded} + R_{det}} =$

$$\frac{1}{\frac{R_{det}}{\pi f\ L_{tank} Q_{unloaded}} + 1}$$

Tank Loss (dB): $10\log\frac{R_{tank}}{R_{tank} + 2R_{det}}$ dB

Tank Loss (%): $\frac{R_{det}}{R_{tank} + 2R_{det}} = \frac{R_{det}}{2\pi f\ L_{tank} Q_{unloaded} + 2R_{det}}$

Circulating Current Losses

The preceding should be valid so long as the tank's Q is limited primarily by its shunt resistance. To check this assumption, verify the tank's circulating current series resistance (R_circ) is

---

at the natural frequency of the LRC circuit, $f_0 = \omega_0/2\pi$. (This last feature might not be completely obvious from the form of the equation if you are not much used to analysing the behaviour of functions.) At its maximum, the amplitude of oscillation of IL is about a factor Q larger than the amplitude of oscillation of I. (Note that $I_{L0} = QI_0$ when $\omega = \omega_0$. The amplitude of IL can exceed that of the total current, I0, because the current passing through the inductor includes a current circulating round the LCR circuit formed by the inductor and the capacitor; this circulating current may be large when $f \approx f_0$.)

This enhancement is an example of a resonance, a common phenomenon in many different fields of Physics and Engineering: When an oscillating system is excited by a periodic perturbation whose frequency (almost) coincides with one of its natural frequencies, the response of the system to the perturbation is greatly magnified when damping is light. (See Young and Freedman [1], Section 14.8, for a short discussion of this matter.)

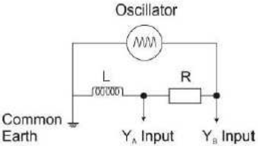


Figure 3: The circuit considered in tasks 1 and 2.

One also sees from Equation (20) that when the frequency of the generator sweeps through the resonance, the phase of the common feature of the evolution of dissipative systems kicked away from their equilibrium position by a sudden perturbation.

The steady state solution is particularly interesting when the total current generated by the signal generator varies sinusoidally. Setting $I = I_0 \cos(\omega t)$, as given by Equation (2), Equation (15) now reads

$$LC\frac{d^2 I_L}{dt^2} + rC\frac{dI_L}{dt} + I_L = I_0 \cos(\omega t) \qquad (18)$$

This last equation can also be solved exactly using general methods (which you will study in your Maths course). Doing so results in the following steady state solution:

$$I_L = I_{L0}\sin(\omega t - \phi) \qquad (19)$$

where the phase-angle f is defined by the equation

$$\tan\phi = Q\frac{\omega^2 - \omega_0^2}{\omega\omega_0} \qquad (20)$$

and

$$I_{L0} = \frac{I_0}{\sqrt{\frac{1}{Q^2}\frac{\omega^2}{\omega_0^2} + \left(\frac{\omega_0^2 - \omega^2}{\omega_0^2}\right)^2}} \qquad (21)$$

Equation (19) shows that in the steady state the current through the inductor oscillates at the frequency of the signal generator, $f = \omega/2\pi$. Equation (21) tells us that when the Q-factor is much larger than 1, then, as a function of f, IL strongly peaks

much lower than what it would need to be to be solely responsible for the LC tank's unloaded Q.

$$R_{\circ} << \frac{2\pi f\, L_{tank}}{Q_{unloaded}} = \frac{1}{2\pi f\, C Q_{unloaded}}$$

For the 'worst case' broadcast band values, this series resistance is small, but not impossible to beat.

$R_{\circ} << \frac{2\times\pi\times f\ \times 90\times 10^{-6}}{1000} \approx$ 0.3 Ω at 520 kHz, and 1 Ω at 1720 kHz.

For comparison, the 30' (10 m) of 12 AWG (2 mm) solid wire sufficient to make a stout cylindrical air-core inductor of this value is about 0.05 Ω.

One thing to note is how much circulating current resistance by itself is equivalent to the tank loading resistance (again by itself) resulting in the same tank Q.

$$Q = \frac{R_{tank}}{2\pi f\, L_{tank}} = \frac{2\pi f\, L_{tank}}{R_{\circ}}$$

$$\Rightarrow \quad R_{tank} R_{\circ} = \left(2\pi f\, L_{tank}\right)^2$$

$$R_{tank} = \frac{\left(2\pi f\, L_{tank}\right)^2}{R_{\circ}} \quad ;$$

$$R_o = \frac{\left(2\pi f\ L_{tank}\right)^2}{R_{tank}}$$ [3]

Thus, at 1 MHz, one ohm of circulating current resistance is equivalent to loading a 100 µH tank with about 400 kΩ, while it would load a 200 µH tank only one-quarter as heavily, about 1.6 MΩ. Since parallel loading dominates most crystal radio tank designs, it seems worthwhile to use tanks with smaller inductors. However, parallel loading decreases Q with increasing frequency, and BCB reception requires an increasing Q to maintain constant bandwidth, so some trade-offs may be worth considering.

Now, if it were true that the unloaded tank Q can be modeled accurately from only the inductance (L_tnk) and parallel tank resistance (R_tnk), then the Q should always decrease with frequency, but this is not the case. Perhaps a combination of parallel and serial (circulating) resistance can be used.

$$Q_{unloaded} = \frac{1}{\dfrac{2\pi f\ L_{tank}}{R_{tank}} + \dfrac{R_o}{2\pi f\ L_{tank}}}$$

Tank Design

Typical ferrite toroid inductor Q is 300.[4]
Extremely good tanks have R_tank increasing from 1 MOhm to 2 MOhm across the broadcast band.[5]

[1] Q-Factor

$$LC\frac{d^2 I_L}{dt^2} + rC\frac{dI_L}{dt} + I_L = I \qquad (15)$$

The solutions of this equation will depend on how the total current I varies in time. For a square wave signal, I can be taken to jump rather abruptly, but periodically, from one value to another, staying constant between the jumps. Between any two consecutive jumps, the time evolution of IL is thus governed by the equation

$$LC\frac{d^2 I_L}{dt^2} + rC\frac{dI_L}{dt} + I_L = I_0 \qquad (16)$$

where I0 is a constant. The relevant solution of this equation is

$$I_L = A\exp(-\alpha t)\cos(\omega_0' t + \chi) + I_0 \qquad (17)$$

with the values of the constants A and depending on the precise variation of I during the jumps. (What these values are is not important for us.)

It is clear from Equation (17) that immediately after the jump in I, the current across the inductor oscillates at the natural frequency of the circuit, about a value equal to I0, with an amplitude of oscillation decreasing in time due to the exponential factor. Thus IL tends towards I0, and becomes indistinguishable from I0 once the initial oscillation has sufficiently decrease in amplitude. The time-evolution of IL can thus be divided into two parts: At first, immediately after the jump in I, IL displays transients (the free oscillations), which disappear gradually and leave place to a steady state solution (IL = I0). The occurrence of transients is a very is large (which will be the case for the circuit built in this practical).

As can be easily checked from Equation (10), the amplitude of the oscillation decreases by a factor 2 over any interval of time of duration $\Delta t_{1/2} = \ln 2 / \alpha$, that is, over a number of periods of oscillation equal to $n_{1/2} = \Delta t_{1/2} / T_0$. (We neglect the difference between ω_0 and ω_0'.) Given that $\alpha = r/(2L)$ as noted above, and that $T_0 = 1/f_0$, we have, in good approximation when Q is large,

$$Q = \frac{\pi n_{1/2}}{\ln 2} \qquad (14)$$

This last result will be used in Task 5. An important conclusion one can derive from it is that a large Q-factor means that the oscillations last for a long time, i.e., that the damping is light.

However, the case of interest here is not that of an LRC circuit in isolation but that of Figure 4 below, in which an LRC circuit is connected to other components. In the experiment, the function generator, or "oscillator", may generate a signal which is either a square wave or a sinusoidal wave, and, due to the large resistance of the resistor R, the current flowing through the whole circuit is practically the same as if the capacitor and inductor were not present. We denote by I the total current flowing through the whole circuit. Therefore we now have $I_C + I_L = I$ instead of $I_C + I_L = 0$.

The result is that Equation (9) acquires a non-zero right-hand side and becomes

---

2)

$$Q_{loaded} = \frac{1}{\left(\frac{1}{R_{det}} + \frac{2}{R_{tank}}\right) 2\pi f\, L_{tank}} =$$

$$\frac{1}{\left(\frac{1}{R_{det}} + \frac{2}{2\pi f\, L_{tank} Q_{unloaded}}\right) 2\pi f\, L_{tank}} =$$

$$\frac{1}{\left(\frac{2\pi f\, L_{tank}}{R_{det}} + \frac{2}{Q_{unloaded}}\right)} = \frac{Q_{unloaded} R_{det}}{2\pi f\, L_{tank} Q_{unloaded} + 2 R_{det}}$$

3) This gives the same results as Series - Parallel Impedance Conversion Calculator//.

4) Experiments with Coils and Q-Measurement, Wes Hayward, w7zoi, October, 2007 (Update 01Dec07.)

5) Experiments with LC circuits part 10

$$\omega_0' = \sqrt{\frac{1}{LC} - \frac{r^2}{4L^2}} \qquad (11)$$

[Equations (10) and (11) are not correct when the argument of the square root function is zero or negative; however, we do not need to worry about this as in the practical r, L and C are such that the argument is positive.]

The time evolution described by Equation (10) is a damped oscillation: the current oscillates, now at a natural angular frequency ω_0' rather than ω_0, and the amplitude of the oscillation decreases exponentially in time. The oscillations disappear because the energy they contain is dissipated – here it is dissipated as heat due to the resistance of the coil. The "quality" of an oscillator, i.e., the length of time the oscillations last once started, is usually quantified by a dimensionless parameter denoted Q, the Q-factor of theoscillator. Here Q is given by the equation

$$Q = \frac{2\pi f_0 L}{r} \qquad (12)$$

where f0 is the natural frequency of the circuit as defined above, $f_0 = 1/2\pi\sqrt{LC}$.Thus $Q = \omega_0 L/r$, and, from Equation (11),

$$\omega_0' = \omega_0\sqrt{1 - \frac{1}{4Q^2}} \qquad (13)$$

The displacement of the natural frequency from its zeroresistance value is therefore small when the quality factor

T_0. $f_0 = 1/T_0$, is called the natural frequency of the circuit. (Recall the relations between frequency, angular frequency and period: $T_0 = 2\pi/\omega_0$ and $\omega_0 = 2\pi f_0$.)

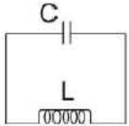

Figure 2: An LC circuit

It is a simple matter to correct Equations (6) and (7) for the internal resistance of the inductor. (With this resistance taken into account, the circuit shown in Figure 3, is a “parallel LRC circuit.) If the resistance of the inductor is r, then $V_L = L\, dI_L/dt + rI_L$, so that Equation (6) now gives

$$LC\frac{d^2 I_L}{dt^2} + rC\frac{dI_L}{dt} + I_L = 0 \qquad (9)$$

This last equation has exactly the same form as the equation of motion of a classical harmonic oscillator for the case where the oscillating mass is submitted to a frictional force proportional to its velocity – see, e.g., Section 14.7 of Young and Freedman [1]. The equation can be solved analytically using general methods. The result is that

$$I_L = A\exp(-\alpha t)\cos(\omega_0' t + \chi) \qquad (10)$$

where A and are two arbitrary constants (i.e., two constants which can have any value), a = r / (2L) , and

---

MEASURING THE Q OF LC CIRCUITS

Dick Kleijer crystal-radio.eu
http://www.crystal-radio.eu/enqmeting.htm

In theory we can determine the Q of a circuit as follows:

Step 1

Couple a RF signal generator to the LC circuit.The coupling between generator and LC circuit must be loose, otherwise the output resistance of the generator will load the circuit and reduces the Q.

Step 2:

Set the generator to the frequency at which you want to measure the Q.Adjust the LC circuit (turn the tuner capacitor) so you have maximum voltage over the circuit, the circuit is now in resonance, this frequency is the resonance frequency of the circuit (f.res).

Step 3:

Measure the voltage over the LC circuit at resonance frequency (f.res).

Step 4:

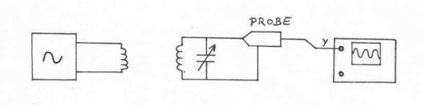
Vary the generator frequency a little above and below f.res. and determine the two frequenties were the voltage over the circuit is 0.707 times the value at f.res.The voltage reduction to 0.707 times, is the -3 dB point.One -3 dB point, is lower in frequency then f.res, this frequency we call: fl.The other -3 dB point is higher in frequency then f.res, this frequency we call: fh.

Step 5:

Calculate the bandwidth BW: **BW= fh - fl.**Calculate the Q: **Q= f.res / BW**

For performing these 5 steps, we can use the following test setup

Test setup 1 Measuring the Q with a signal generator and a probe.



In the schematic above you see from left to right the following components.
A signal generator
A coupling coil
The LC circuit
A 1:100 oscilloscope probe
A oscilloscope

Connect the output of the signal generator to the coupling coil having e.g. 50 turns.
Place the coupling coil at about 20 cm from the coil of the LC circuit.
The coupling coil don't have to be high Q.

These currents and voltages and the charge of the capacitor may vary in time. The instantaneous voltage across the capacitor is given by $V_C = q/C$. Since $I_C = dq/dt$ and $I_C = -I_L$, we can write

$$C\frac{d}{dt}(V_C) = -I_L \tag{6}$$

From Equation (1), we also have VL= L dIL/dt. (As above, we assume that there is no significant potential drop across the coil originating from its internal resistance.) Since C L V =V , we arrive at the equation

$$LC\frac{d^2 I_L}{dt^2} = -I_L \tag{7}$$

You may recognize from the Foundations course that this equation has exactly the same form as the equation of motion for a mass attached to a spring and sliding on a frictionless table (see Chapter 14 of Young and Freedman [1]). Its solutions have thus the same mathematical properties as the solutions found in the mechanical problem, although the Physics context is completely different. Therefore IL (and thus q, IC, VC and VL) oscillate harmonically in time, i.e., like a sin or a cos function. Repeating the calculation done for the mechanical harmonic oscillator, one finds that the angular frequency of these oscillations is

$$\omega_0 = \sqrt{\frac{1}{LC}} \tag{8}$$

and that their period, T_0. is $2\pi\sqrt{LC}$. The inverse of

$$V_L = -\omega L I_0 \sin(\omega t) = \omega L I_0 \cos(\omega t + \pi / 2) \tag{4}$$

Comparing equations (2) and (4), we see that the maxima of VL occur a time $\pi/(2\omega)$ before the maxima I, i.e. a quarter of a cycle earlier: one says that the voltage leads the current by 90 degrees.

From the last two equations we also see that the maximum of the voltage across the inductor, V_L^{MAX}, is $\omega L I_0$, while the maximum of the voltage across the resistor, V_R^{MAX}, is RI_0. We thus have

$$V_L^{MAX} = \left(\frac{\omega L}{R}\right) V_R^{MAX} = \left(\frac{2\pi f L}{R}\right) V_R^{MAX} \tag{5}$$

This relation will be used in Task 2 to obtain the inductance of the inductor provided. Let us now consider the circuit shown in Figure 2. To begin, we'll assume that the resistance of the wires connecting the capacitor and the inductor and the resistance of the wire forming the inductor (its internal resistance) are both negligible. The voltage across the capacitor and the voltage across the inductor will be denoted by VC and VL, respectively, the capacitance and inductance of these two components by C and L, the current flowing through the capacitor by IC, that flowing through the inductor by IL, and the charge of the capacitor by q. For convenience, we measure VC , VL , IC and IL from left to right. Hence VC =VL and C L I = -I . (To see why there is a minus sign in the last equation, note that the current must flow in opposite directions in the upper and lower parts of the circuit.)

Because of the 20 cm distance, there is a loose coupling between the coils.

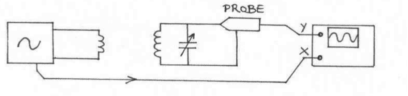
Connect the probe to the LC circuit.
The earth connection of the probe must be connected to the housing of the tuner capacitor.
The probe is connected to the oscilloscope.
The probe provides a small loading of the circuit, so the Q will not reduce so much.
There are also 1:1 and 1:10 probe's, but these will load the LC circuit too much.
The 1:100 probe I use has a input resistance of 100 M.Ohm, and a input capacity of 4 pF.

The output voltage of the generator must be set so high, that the oscilloscoop gives a clear picture of the RF signal.
Because the 100 times attenuation in the probe, the signal generator output must be set fairly high.
When measuring low Q circuits, I must set the generator output to it's maximum of 20 Volt peak-peak.

For measuring the Q: perform the 5 steps described on the top of this page.

The frequency adjustment is done by hand, by turning the frequency knob of the generator.

Test setup 2 Measuring the Q with a sweep generator and a probe.



In this schematic you see from left to right the following components:

A sweep signal generator
A coupling coil
The LC circuit
A 1:100 oscilloscope probe
A oscilloscope

This method uses a sweep generator, this is a signal generator where the frequency is constant varying between two set values.
I use a sweep function generator of brand "Hung Chang" with model number G305, it can produce signals up to 10 MHz.
It has a "sweep output" which gives a voltage going up and down with the frequency sweep.

The "sweep output" is connected with the X input of the oscilloscope, the oscilloscope is placed in the X-Y mode.
Now the lightspot on the scope runs from left to right and back over the screen, this makes a frequency scale with on the leftside the startfrequency and on the rightside the stopfrequency of the sweep generator.
The sweepfrequency must be set at about 10 Hertz, this means the frequency is running 10 times per second from startfrequency to stopfrequency and back.

The Y input of the oscilloscope is connected via the 1:100 probe with the LC circuit.

The RF output of the sweep generator is connected to the coupling coil, which is placed about 20 cm from the coil of the LC circuit.

L is always positive. Hence, when the current increases, so does the potential drop across the coil, which means that the coil effectively opposes the increase in current. Likewise, when the current decreases, the potential difference across the coil is negative, which tends to increase the current and opposes its change. These effects are a manifestation of Lenz's law, which states, in the words of Young and Freedman [1], that 'the direction of any magnetic induction effect is such as to oppose the cause of the effect'.

The coil does not act like a resistor following Ohm's law, though, since VL is proportional to the rate of change in current, not to the current itself. For instance, consider the LR circuit of Figure 1. We'll denote the inductance of the inductor by L, the resistance of the resistor by R, and the frequency of oscillation of the emf produced by the function generator (or oscillator) by f. The values of L, R and f relevant in this practical are such that the total potential drop across the circuit is dominated by the drop across the resistor, which means that the current flowing through the circuit, I, is almost the same as if the inductor was not present. Let us thus assume that

$$I = I_0 \cos(\omega t) \tag{2}$$

with I0 a constant and Then, if VR is the voltage across the resistor, we have, by Ohm's law

$$V_R = RI = RI_0 \cos(\omega t) \tag{3}$$

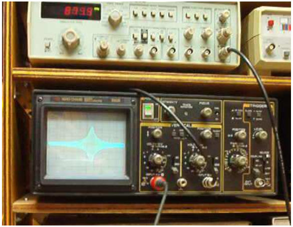
If the resistance of the wire forming the inductor is negligible, then the potential difference between its two ends, VL, is identical to the voltage induced by the change of current, Vind. In this case, from Equation (1), happens when the circuit enters resonance. By the end of the practical you will have seen how resonant circuits can be used to tune radios.

While the work will focus on measurements on a relatively simple circuit, it actually addresses the general issue of how “under-damped” oscillating systems behave when subjected to a periodic perturbation, which is an issue of wide significance in Physics and Engineering. The main features of the currents and voltages measured during the session – their free damped harmonic oscillation, the excitation of transients by a sudden perturbation, the occurrence of resonances under a periodic forcing, and the dependence of the height and width of the resonance peaks and of the accompanying phase changes on the Q-factor of the system – are in fact quite general. They are found in any physical system governed by the same type of differential equations as the LRC circuit considered here.

2. Preparation

A current passing through a coil produces a magnetic field – this is the principle of electromagnets and transformers. If this current changes as a function of time, then so does the magnetic field. As you will see in the Foundations course, the change in the magnetic field present inside the coil induces a potential difference Vind between the two ends of the wire forming the coil, and this potential difference is proportional to the rate of change in the current [1]. By definition, the inductance of the coil (or more generally, of an inductor) is the quantity L such that

$$V_{\text{ind}} = L\frac{dI}{dt} \qquad (1)$$



At the top: the sweep signal generator.

Under: oscilloscope with the curve of the LC circuit on the screen.

We can turn the tuner capacitor and get the curve of the LC circuit on the oscilloscope screen.
Adjust with the amplitudeknob of the sweep generator the hight of the peak of the curve to 2.83 cm.
(The peak-peak distance is then: 2x2.83=5.66 cm).

Determine the width of the curve at 2 cm high, this is the -3 dB point (because 2.83x0.707= 2).

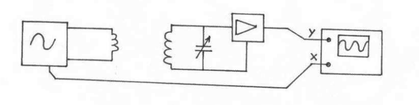
Calculate the bandwidth:
BW= (stopfrequency-startfrequency) x curve width at -3 dB / total screenwidth.

And the Q:
Q= f.res / BW

The great advantage of this method is that changes in resonance frequency of the LC circuit, can direct be seen on the screen.
Also changes in Q can direct be seen, because the hight of the peak will change then.

At high Q circuits, we can see the hight of the peak halve for instance, when we touch the (insulated) litzwire with our fingers.

Test setup 3 measuring the Q with a sweep generator and a amplifier.



In this schematic we see from left to right the following components:

A sweep signal generator
A coupling coil
The LC circuit
A amplifier
A oscilloscope

When using a 1:100 probe between LC circuit and oscilloscope there are two problems:

a- Because the 100 times attenuation of the signal, the amplitude on the oscilloscope will often have a very low level.
b- The probe can give dielectric losses, which reduces the Q.

To solve these two problems, I replaced the probe by a selfmade amplifier with a gain of 1x.
The amplitude on the oscilloscope will now be 100 times higher then with the 1:100 probe.

Question: Compare this last equation to Equation (18) of Section 2, and show, by identifying the constants between these two equations, (i) that, within a change of notation and of physical dimensions, the amplitude IL0 defined by Equation (21) is nothing else than the amplitude A defined by Equation (14.46) of Young and Freedman; and (ii) that the ratio b / km is the inverse of the Q-factor of the harmonic oscillator. (Hence, in Figure 14.28 of Young and Freedman, the amplitude A is more and more peaked at the resonance for higher and higher values of the Q-factor.)

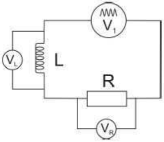


Figure 1: The LR circuit considered in Section 2.

1.What it’s about

This session explores the behaviour of “LRC circuits”, also known as “LCR circuits” and “RLC circuits”, namely circuits containing resistors (R), inductors (L) and capacitors (C). It builds on the second Circuits Skills experiments, in which you looked at circuits containing resistors and capacitors and measured voltages using an oscilloscope. Here the objective of your measurements will be to find the inductance and internal resistance of an inductor and the Q-factor and frequency of oscillation of an LRC circuit. In the process, you will investigate the response of a driven LRC circuit to different frequencies, look at the effect of damping, and see what

Oscillations and Resonances in LRC Circuits

Durham University, UK
http://level1.physics.dur.ac.uk/projects/script/lcr.pdf

Preparatory Task:

Read the entire script and familiarise yourself with the objectives of the session. In particular, read through Section 2 in advance of the session, as the theory developed in this section is essential for understanding the Physics behind the results you'll obtain. You also need to write in your lab book a brief plan of what you will be doing, task by task, and answer the question below. This practical will involve measuring timedependent voltages with an oscilloscope, error analysis, plotting diagrams (with error bars), and least square fitting using the LINEST function of Excel. If you are not confident in having already acquired the necessary skills in these matters, make use of the online resources available at the url http://level1.physics.dur.ac.uk/general/index.php.

In Sections 14.7 and 14.8 of Young and Freedman [1], you'll find a discussion of the dynamics of a damped harmonic oscillator consisting of a mass m sliding on a table under the effect of a spring of force constant k, a frictional force proportional to the velocity of the mass, and an additional force varying with time sinusoidally. In the notation of Young and Freedman, the equation of motion for the position of the mass is

$$m\frac{d^2x}{dt^2} = -b\frac{dx}{dt} - kx + F_{\max}\cos\omega_d t$$

This equation can also be written in the equivalent form

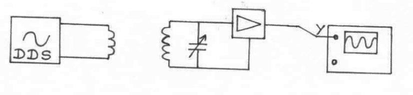
$$\frac{m}{k}\frac{d^2x}{dt^2} + \frac{b}{k}\frac{dx}{dt} + x = \frac{1}{k}F_{\max}\cos\omega_d t$$

The input of the amplifier uses a FET (Field Effect Transistor) and a capacitive voltage divider, which will load the circuit only very little.

A complete schematic of the amplifier you will find here

For the rest, this test setup is the same as test setup 2.

test setup 4 Measuring the Q with a DDS signal generator and a amplifier.



In this schematic you see from left to right:

A DDS signal generator
A coupling coil
The LC circuit
A amplifier
A oscilloscope

DDS means "Direct Digital Synthesis".

The output signal is in a DDS generator made in a digital way.
The great advantage of this kind of generator is the accuracy of the frequency setting.
The output has also a very low distortion.
The DDS generator I use, is a build yourself electronic kit from the company ELV .
You can also buy a complete build and tested module.

The specification are:

Output frequency: 0.1Hz -- 20 MHz.
Output voltage: 0 -- 4 Volt peak peak (not loaded).
Output impedance: 50 Ohm.
Minimum stepsize of frequency setting is 0.1 Hz. (up to 10 MHz output frequency).
Minimum stepsize of frequency setting is 1 Hz. (10 to 20 MHz output frequency).

As stepsize you can also select, e.g. 10 Hz, 100 Hz, 1 KHz, etc.

I now use the DDS generator because the used sweep generator could not be set accurate enough on frequency.
And also the frequency changes slightly during the measurement.

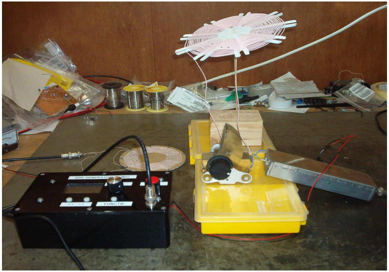


Photo of the test setup.
The coil laying on the table is the coupling coil.

You can get an accurate measure of the width by finding the frequencies just above and just below the resonance at which vC is reduced by $1/\sqrt{2}$ from the peak value. The width $\Delta\omega$ is then $2\pi\Delta f$, where the 2π converts from frequency in Hertz to angular frequency. Do your measured values of $\Delta\omega$ and τ satisfy Eq. 12?

The FET amplifier is connected via short wires to the tuner capacitor.
The coil of the LC circuit is placed at the top of a wooden stick, so it has not much influence from surrounding obstacles.

The windings are laying in a horizontal plane, so the coil picks up less signal from radiostations which can influence the measurement.

During measurements on high Q circuits, I tune the DDS generator in 10 Hz steps.
This test setup is in my opinion very reliable for determining the circuit Q.

Tips for measuring the Q:

During measurements don't come with your hands too close to the LC circuit, because this has influence on frequency and Q.
Keep a minimum distance of 20 cm.

Don't lay the coil of the LC circuit during measurement on the table, but keep a minimum distance of 20 cm from wooden or metal objects.

Driven oscillations

To study the driven solution we need to provide a sine-wave signal source, as shown in Fig. 5. Our source is equivalent to an ideal sine-wave generator in series with a 50 resistor, labeled Rg in the diagram. Since Rg is large enough to affect the damping of the circuit, we add the 3.3 ! resistor in parallel to reduce the effective resistance of the generator. The other change from Fig. 4 is to replace the LabPro with a DMM, set to read AC voltage. (The DMM can read AC voltages between about 30 Hz and 1000 Hz. It is unreliable outside of that range.)

Connect the circuit as shown in Fig 5, and then vary the driving frequency to find the frequency at which vC is maximum. This identifies the resonance frequency, in Hertz. Next, you should plot vC as a function of frequency, taking care to get enough data around the resonance frequency to clearly define the curve. This goes very quickly if you enter f and vC directly into Graph.cmbl and then pick data points to trace the regions of interest. Does your plot look like Fig.3?

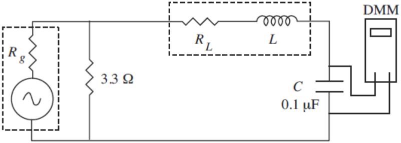

Fig. 5 Circuit for measuring driven oscillations in an RLC circuit.

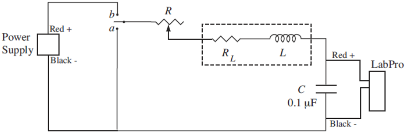

Fig. 4 Circuit for measuring free oscillations in an RLC circuit.

a will start the discharge, and should result in a plot resembling Fig. 2. There may be some irregularity at the beginning, due to bouncing when the switch first makes contact, but you can ignore that in your analysis.

When you have a reasonable looking plot, select the portion of the data after any effects of switch bounce, and fit it to a damped sine wave. You should be able to obtain estimates of the time constant and the angular frequency for your circuit. (Delete the fit or restart RLC.cmbl before taking more data. Otherwise you will have to wait while the program tries to fit the new data.)

Now increase the variable resistor R slightly and obtain another voltage vs time plot. Describe what happens to the time constant and to the shape of the curve as R becomes progressively larger.

Critical damping occurs when R is just big enough that the voltage no longer crosses zero during the decay. Try to find this setting, and measure the value of the variable resistor using a DMM. The exact value is not very clear, but make a reasonable attempt. Reminder: You must disconnect R from the circuit to get an accurate measurement with the DMM.

Q Factor Measurements on L-C Circuits

Jacques Audet, VE2AZX
http://www.arrl.org/files/file/QEX_Next_Issue/Jan-Feb_2012/QEX_1_12_Audet.pdf

The author reviews existing measurement techniques and offers insight into loaded and unloaded Q factors as applied to LC circuits and antennas. A simpler method is proposed that uses an SWR analyzer along with a spreadsheet that easily computes the unloaded Q.

Introduction

The Q factor gives a figure of merit for inductors and capacitors. It is the ratio of reactance to resistance. For filters, it relates directly to the circuit selectivity: The higher the Q, the better the selectivity and the lower the insertion loss of the filter. For oscillators, higher Q also means that lower phase noise is produced. In the case of antennas, a lower Q is generally preferred, giving a larger SWR bandwidth.

Transmission methods are traditionally used for making quality factor (Q) measurements on L-C circuits. This implies that a signal source and an RF voltmeter or spectrum analyzer must be available for such measurements. These are not always available however. Since SWR analyzers are becoming commonplace in many amateur radio rooms, it then becomes tempting to use this instrument for Q measurements on L-C circuits.

Let’s review the existing methods that are currently used for Q measurements that only require scalar measurements — that is, no phase measurements are required. The last method details how the SWR analyzer can be used to measure the unloaded Q of L-C circuits.

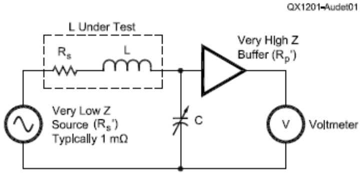

Figure 1 — Block diagram of the classical Q meter as used in the HP 4342A.

1 – The Classical Q Meter Method

This is the technique you would use if you had access to a Q Meter, such as an HP / Agilent Q Meter model HP 4342A. See Figure 1. A very low impedance source is required, typically 1 milliohm, and a very high impedance detector is connected across the L-C circuit. The unloaded Q (QU) of a single reactance component is given by Equation 1.

$$Q_U = \frac{X_S}{R_S} = \frac{R_P}{X_P} \quad \text{[Eq 1]}$$

where XS and RS are the series reactance and loss resistance, and RP and XP are the corresponding parallel loss resistance and reactance components.

In the test set-up we need to make the source resistance RS′ as small as possible, since it adds to the coil or capacitor resistance. Similarly, the detector resistance, RP′ shunting

---

demonstrating the intimate relation between time and frequency response parameters. In obtaining this result, we assumed , so that at the peak.

EXPERIMENTAL PROCEDURE

The RLC circuit is assembled from a large solenoid, a capacitor on the circuit board, and an additional variable resistance to change the damping. The circuit can be charged up with a DC power supply to study the free oscillations, or driven with a sine wave source for forced oscillations.

Free oscillations

To study the homogeneous solution we will use LoggerPro to record the voltage across the capacitor as a function of time. The required circuit is shown in Fig. 4. Since the coil is not made with superconducting wire, we account for the wire resistance with RL. The variable resistor, shown by a resistor symbol with an arrow in the middle, should be set to minimum resistance initially. (You can check with the DMM in ohmmeter mode, before connecting R into the circuit.) The power supply can be set to maximum output.

Start LoggerPro with the file RLC.cmbl. This will configure the program to collect data at 10,000 samples per second, triggered when the voltage decreases across 9.5 V. Set the switch to position b to charge the capacitor, and then start data acquisition. Flipping the switch to position

At the maximum, the oscillation amplitude is considerably greater than the driving amplitude. In fact, if τ were infinite (no damping), the response would be infinite at ω_0.

Since the shape of the peak in vC characterizes the resonance, it is convenient to have some parameter to specify the sharpness of the peak. Traditionally, this is taken to be the full width $\Delta\omega$, shown in Fig. 3, at which the voltage or current have fallen to $1/\sqrt{2}$ of their peak value.

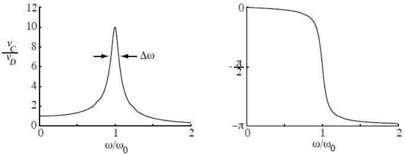

Fig. 3 Amplitude and phase of capacitor voltage as a function of frequency.

The reason for this choice is that the power dissipation is proportional to i^2, so these frequencies correspond to the points at which the power dissipation is half of the maximum. Using Eq. 9 we find that the width is related to τ by

$$\Delta\omega = \frac{2}{\tau} \quad (12)$$

the L-C should be much higher than the RP of the component under test. Note that the L-C circuit is commonly represented as having a resistor in series (RS) with L and C or a shunt resistor (RP) in the parallel model to represent the losses.

Measurement consists of setting the source frequency and adjusting the tuning capacitor, C, for resonance to maximize the voltage across the resonating capacitor C. The Q is calculated using Equation 2.

$$Q = \frac{\text{Voltage Across } C}{\text{Source Voltage}} \quad \text{[Eq 2]}$$

Note that the source voltage is in the millivolt range, since it will be multiplied by the Q factor. A 10 mV source and a Q of 500 will give 5 V across the L-C circuit. In order to preserve the high impedance of the detector even at the higher frequencies, a capacitive voltage divider is used.

This circuit measures the unloaded Q called QU provided that the series resistance RS of the inductor under test is much higher than the source resistance RS′ and the detector parallel resistance RP′ is much larger than the L-C circuit RP.1

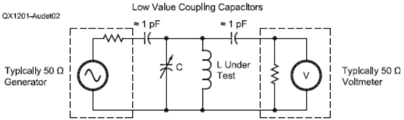

Figure 2 — The signal generator and the source are weakly coupled to the L-C circuit under test, allowing measurement of the 3 dB bandwidth.

2 – Transmission Method Using Coupling Capacitors

A signal is coupled into an L-C parallel circuit using a low value capacitor and extracts the output signal using the same value of capacitor.2 See Figure 2. Note that inductive coupling is also possible, as used in transmission line (cavity) resonators. The – 3 dB bandwidth (BW) is measured at the resonant frequency f0, and the loaded Q (QL) is calculated with Equation 3.

$$Q_L = \frac{f_0}{BW} \quad \text{[Eq 3]}$$

The obtained bandwidth, BW, is a function of the coupling, and another calculation is required to get QU, the unloaded Q. When the input to output coupling is identical, we use Equation 4.

$$Loss = 20\log\left(\frac{Q_U}{Q_U - Q_L}\right) \quad \text{[Eq 4]}$$

where Loss is in positive dB. The ratio QU / QL may now be calculated using Equation 5.

$$\frac{Q_U}{Q_L} = \left(\frac{10^{\frac{Loss}{20}}}{10^{\frac{Loss}{20}} - 1}\right) \quad \text{[Eq 5]}$$

1/# is referred to as "critical damping" because the charge reaches zero in the shortest time without changing polarity.

The solution for sine-wave driving describes a steady oscillation at the frequency of the driving voltage:

$$q_C = A\sin(\omega t + \phi) \quad (8)$$

We can find A and ϕ by substituting into the differential equation and solving:

$$A = \frac{v_D / L}{\left[\left(\omega_0^2 - \omega^2\right)^2 + \left(2\omega / \tau\right)^2\right]^{1/2}} \quad (9)$$

$$\tan\phi = \frac{2\omega / \tau}{\left(\omega^2 - \omega_0^2\right)} \quad (10)$$

These two equations are plotted in Fig. 3, where we use the fact that $v_C = q_C/C$ to plot the voltage across the capacitor relative to the driving voltage. (Our apparatus does not allow us to observe the phase of the response, so we won't consider that further.) The angular frequency for maximum amplitude is given by

$$\omega_{peak} = \omega_0\left[1 - 2/\left(\omega_0\tau\right)^2\right]^{1/2} \quad (11)$$

Where qC0 and ! are determined by initial conditions, and

$$\omega_1 = \omega_0\left[1 - (\omega_0 \tau)^{-2}\right]^{1/2} \quad (5)$$

This solution is plotted in Fig. 2 for a case where the capacitor is initially charged and no current is flowing. (For a mass on a spring the equivalent situation would be to pull the mass aside and release it from rest.) Evidently there are oscillations at ω_1, approximately equal to ω_0, within an exponential envelope. Note that the amplitude falls to 1/e of the initial value when $t = \tau$.

As $\omega_0 < 1/\tau$ gets smaller (larger resistance R), ω_1 becomes smaller and finally imaginary. The corresponding solutions do not oscillate at all. For $\omega_0 < 1/\tau$, there are two exponentials

$$q_C = A_1 e^{-t/\tau_1} + A_2 e^{-t/\tau_2} \quad (6)$$

where τ_1 and τ_2 differ somewhat from τ. When $\omega_0 = 1/\tau$, the solution is slightly simpler:

$$q_C = \left(A_1 + A_2 t\right) e^{-t/\tau} \quad (7)$$

If the capacitor is initially charged, these results tell us we will get a monotonic decay for sufficiently large R. The case "0 =

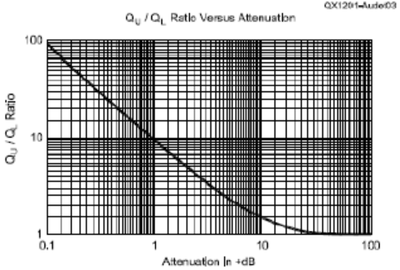

Figure 3 — Graph showing the ratio of unloaded Q (QU) to loaded Q (QL) as a function of the L-C circuit attenuation at resonance. Applies to a single tuned circuit with identical in / out coupling. When the attenuation is large (> 20 dB) the coupling is minimal and the loaded Q closely approaches the unloaded Q.

This equation is plotted in Figure 3. Note that this method applies well to transmission line resonators with equal impedance inductive coupling loops at the input / output. Note also that these two methods do not require knowledge of the L or C values to compute the Q factors.

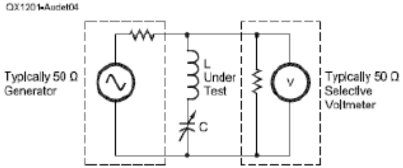

Figure 4 — Here the L-C circuit is connected in series and across the generator - detector. At resonance the L-C circuit has minimum impedance and by measuring the attenuation, the effective series resistance ESR of the L-C series may be computed at the resonant frequency f0.

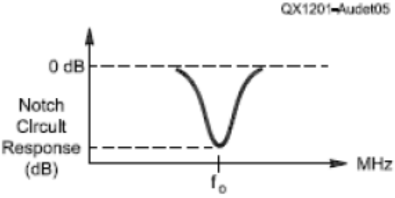

Figure 5 — Frequency response of the notch circuit of Figure 4, where f0 is the frequency of maximum attenuation.

3 – Shunt Mode Transmission Method With L-C in Series

with $\tau = 2L/R$ and $\omega_0^2 = 1/LC$. Two situations will be of interest. We will examine the free oscillations, when vD is exactly zero, meaning that the sine-wave generator has been replaced with a short circuit. We will then connect the sine wave generator and calculate the response as a function of frequency.

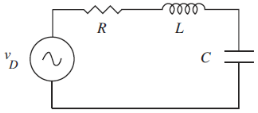

Fig. 1 Idealized series RLC circuit driven by a sine-wave voltage source.

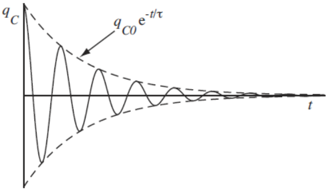

Fig. 2 Damped oscillation, showing decay envelope

If the resistance in the circuit is small, the free oscillations are of the form

$$q_C = q_{C0}e^{-t/\tau}\cos(\omega_1 t + \phi) \quad (4)$$

RLC Circuits
Rice University

It doesn't matter how beautiful your theory is, it doesn't matter how smart you are. If it doesn't agree with experiment, it's wrong.
Richard Feynman (1918-1988)

OBJECTIVES

To observe free and driven oscillations of an RLC circuit.

THEORY

The circuit of interest is shown in Fig. 1, including sine-wave sources. We start with the series connection, writing Kirchoff's law for the loop in terms of the charge qC on the capacitor and the current $i = dq_C/dt$ in the loop. The sum of the voltages around the loop must be zero, so we obtain

$$v_L + v_R + v_C = v_D \sin(\omega t) \quad (1)$$

$$L\frac{d^2q_C}{dt^2} + R\frac{dq_C}{dt} + \frac{q_C}{C} = v_D \sin(\omega t) \quad (2)$$

For reasons that will become clear shortly, we rewrite this as

$$\frac{d^2q_C}{dt^2} + \frac{2}{\tau}\frac{dq_C}{dt} + \omega_0^2 q_C = \frac{v_D}{L}\sin(\omega t) \quad (3)$$

Here the L and C are series connected and placed in shunt across the transmission circuit. See Figure 4. (This method is also detailed in the reference of Note 2.) It basically computes the effective series resistance (ESR) of the combined L and C, based on the attenuation in dB at resonance, using a selective voltmeter to prevent source harmonics from affecting the measurement. The ESR may be calculated using Equation 6.

$$ESR = \frac{Z}{2\left(10^{\frac{dB}{20}} - 1\right)} \quad \text{[Eq 6]}$$

where dB is a positive value of attenuation and Z is the source and detector impedance. Once the ESR is known, it is only necessary to compute:

$$Q_U = \frac{X_L}{ESR} \quad \text{[Eq 7]}$$

where XL = 2π f0L, and L has already been measured separately.

Note 3 gives a reference to a spreadsheet that I have developed to eliminate the need to measure L and C. Two more attenuation points are required to compute these values. There is also a version for crystals, which computes the equivalent R L C values and other related parameters.

4 – Reflection Measurement Using an SWR Analyzer

This method has been recently developed to make use of an SWR analyzer, thus eliminating the need for the source detector combination. Adjust the SWR analyzer to the resonant frequency of the circuit. The L-C circuit may be coupled to a link coil on the SWR analyzer, which provides variable coupling. As shown in Figure 7, the amount of coupling is adjusted until the SWR drops to 1:1. The frequency is recorded as f0. Then the frequency is offset above or below f0 to obtain an SWR reading between 2 and 5. Now plug the new frequency and SWR values in the spreadsheet that I provide to calculate the unloaded Q factor. Note that the L or C values are not required to compute the Q factor.

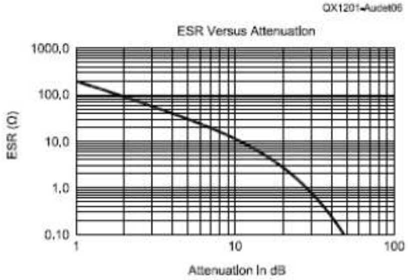

Figure 6 — Effective series resistance as computed from the attenuation in dB, in a 50 Ω system.

When $R = 0 \Rightarrow R_{total} = R_p \Rightarrow R_p = \beta_{exp} \cdot 2L$

3. Calculate experimental angular frequency of oscillations

$$\omega_R = \frac{2\pi}{T}$$

4. For the resonance conditions in RLC circuit, calculate capacitance C for each inductance L using the equations:

5. Calculate the uncertainty of the capacitance _C

6. For the case of critical damping, compare the experimental value of critical resistance RC with its theoretical value calculated on the basis of the equation:

$$R_{Ctheory} = 2\sqrt{\frac{L}{C}}$$

7. Write the conclusions.

Literature:

1. Halliday, Resnick “Fundamentals of Physics - 8th edition”, John Wiley 2007

2. Zięba “Pracownia Fizyczna Wydziału Fizyki I Techniki Jądrowej AGH”, Uczelniane Wydawnictwo Naukowo-Dydaktyczne 1999.

Updated: 11.02.2011 by Barbara Dziurdzia resistor and repeat the observations. Investigate how the increase in resistance R affects the oscillation parameters.

6. Increase R until the critical aperiodic oscillations occur and write down the Rcritical in the measurement table.

7. Change the inductance to L2 at the decade coil and for resistances R0=0, R1, R2 repeat all measurements according to 2-6. Investigate how the increase in inductance L affects the oscillation parameters.

8. Write down the results in Table 1.

6. Data Handling

1. Calculate the log decrements $\delta = \ln\left(\frac{U_i}{U_{i+2}}\right)$ and the experimental damping coefficient β exp of oscillations: $\beta_{\exp} = \frac{\ln \frac{U_i}{U_{i+2}}}{T}$ for all combinations (L1, R0), (L1, R1), (L1, R2), (L2, R0), (L2, R1), (L2, R2)

2. Calculate the parasitic resistance of a coil Rp taking advantage from the fact that at the beginning there is always set R=0 at the resistance decade. the total resistance Rtotal in the RLC circuit consists of the resistance of a decade R and the parasitic resistance of a coil R_p: $R_{total} = R + R_p$.

$$\beta_{\exp} = \frac{R_{total}}{2L}, \quad R_{total} = \beta_{\exp} \cdot 2L$$

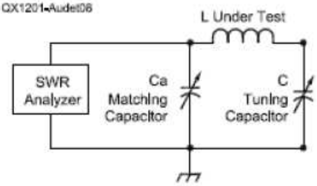
Figure 7 — Set-up for measuring the unloaded Q of L-C resonant circuit. The coupling is adjusted for 1:1 SWR at resonance. The link should have approximately 1 turn per 5 or 10 turns of the inductor under test.



QX1201-Audet06
L Under Test
SWR Analyzer
Ca Matching Capacitor
C Tuning Capacitor

Figure 8 — Here the variable coupling to the SWR analyzer is provided by the capacitive divider formed by Ca and C. Ca is typically 10 to 50 times larger than C.

As shown in Figure 8 the coupling may also be realized with a second variable capacitor, Ca, which serves as an impedance divider. Both capacitors have their frame grounded, along with the SWR analyzer. This makes the construction and operation of the SWR - Q meter much easier.

Both circuits transform the L-C circuit effective parallel resistance RP to 50 + j 0 ohm as required by the analyzer to obtain a 1:1 SWR at resonance. The capacitance value of Ca will be in the order of 10 to 50 times the value of C, the main tuning capacitor. A slight interaction will be present between these two adjustments when adjusting for 1:1 SWR.

Note that a variable inductive divider can be used, in series with the inductor under test, instead of the capacitive divider of Figure 8. In this case the SWR analyzer is connected across this variable inductor, which allows matching to the SWR analyzer 50 ohm input. I do not recommend this as the Q of the variable inductor is probably not going to be as high as the matching capacitor, Ca. The Q of these matching components have a second order effect on the measured QU.

At a Q factor of 300, a 1% error in SWR gives a 1% error in Q. Assume that the measured SWR is 4 and the SWR meter has a resolution of 0.1. If the error in SWR is 0.1, then the error in Q is 2.5%. Other errors include the Q of the tuning capacitor, and the Q of the matching component, Ca, or the link coil to a lesser degree.

2. Set the inductance at the decade coil to the certain value L1 . Set the resistance at the decade resistor to R0=0. Observe the damping oscillations on the oscilloscope selecting the proper time base setting and vertical gain.

3. Measure on the oscilloscope display the period of oscillations T (Fig. 8). To increase accuracy, measure periods of a few successive oscillations and calculate the average value which will be further used to get the experimental angular frequency ω exp of oscillations:

$$\omega_{exp} = \frac{2\pi}{T}$$

4. Measure on the oscilloscope display the amplitude of maxima U2, U4, (Fig. 8)

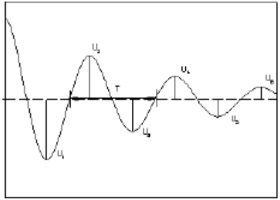


Fig. 8.. Damping oscillations

5. Keep the inductance L1 at the decade coil unchanged and set the another resistance R1 at the decade resistor. Observe the damping oscillations for the settings (L1, R1) and repeat the measurements 3-4. Set the resistance R2 at the decade

connected in series . The oscilloscope monitors the potential difference uC(t) across the capacitor as a function of time.

5. Measurements

1. Set the RLC circuit as shown in Fig. 6 . Fig. 7 shows the decade coil, the decade resistor and the capacitor with its charging system.

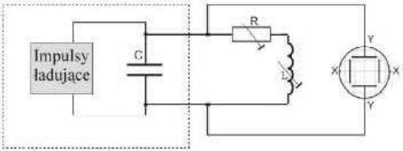

Fig. 6. The measurement system

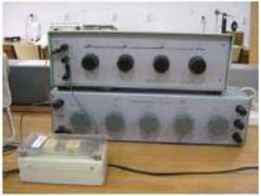

Fig. 7. The decade coil, the decade resistor and the capacitor with its charging system.

Here are some simulation results:

At Q = 200 the average error on the calculated Q is – 0.5% when the test frequency is below resonance. Above resonance, the average error drops to – 0.05%.

At Q = 50 the average error on the calculated Q is –1.0% when the test frequency is below resonance. Above resonance, the average error drops to –0.7%.

These small errors come from the reactance of the coupling element (link coil or Ca in the capacitive divider).

The following errors were obtained by simulation with an inductor Q of 200.

The matching capacitor Ca should have a Q of 500 or larger. A Q value of 500 for Ca gives – 6% error and a Q value of 1000 for Ca gives – 0.6% error. Interestingly the link coil Q may be as low as 50 and the error is only – 0.4%. The losses of the transmission line between the SWR analyzer and the Q measuring circuit should be kept to a minimum. An attenuation of 0.05 dB gives –1.6% error on the calculated Q.

So far the Q factor measurement included both the combined Qs of the L and C, since it is difficult to separate their individual Q values. When the capacitor Q (Qcap) is known the inductor Q (Qind) may be calculated like parallel resistors:

$$\frac{1}{Q_{ind}} = \frac{1}{Q} - \frac{1}{Q_{cap}} \quad \text{[Eq 8]}$$

Note that the combined Q of the L-C circuit is 17% lower with Qind = 200 and Qcap = 1000, compared to having a capacitor with an infinite Q.

Measuring the Q of Low Value Capacitors (< 100 pF) Using the Delta Q Method

Two Q measurements are required:

First measure the Q of a test inductor (preferably having a stable high Q) and record it as Q1 and record the amount of capacitance C1 used to resonate it.

Second, connect the low value capacitor to be tested across the tuning capacitor, decrease its capacitance to obtain resonance again. Note the measured Q as Q2 and the amount of capacitance C2 used to resonate. (Q2 should be less than Q1). Compute the Q of this capacitor as follows:

$$Q = \frac{(C_1 - C_2) \times Q_1 \times Q_2}{C_1 \times (Q_1 - Q_2)} \quad \text{[Eq 9]}$$

Note that (C1 – C2) is the capacitance of interest. It may be measured separately using a C meter. If Q2 = Q1 the Q of the capacitor becomes infinite.

Unloaded and Loaded Q

Looking back at method 1, the measured Q is the loaded Q and it approaches the unloaded Q as the source impedance goes toward zero and the detector impedance is infinite.

With method 2, the measured Q is the loaded Q and a correction is required based on insertion loss to obtain the

---

For damped oscillations, the log decrement is equal to:

$$\delta = \ln\left(\frac{V_1}{V_2}\right) = \frac{R}{2L}T$$

Critical damping in an RLC circuit is achieved when:

$$\frac{1}{LC} - \left(\frac{R}{2L}\right)^2 = 0,$$

from which we obtain:

$$R_{critical} = 2\sqrt{\frac{L}{C}}$$

We vary the resistance and search for a signal that has no undershoot and has a maximum decay rate. Typical oscilloscope traces for the overdamped, underdamped and critical damping are shown in Fig. 5.

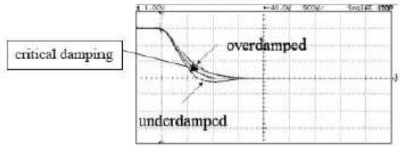

Fig. 5. Typical oscilloscope traces for critical damping critical damping

4. Equipment

RLC circuit consists of a capacitor C combined with its charging system, a decade resistor and a decade coil – all

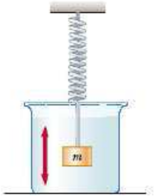

Fig. 3. A mechanical analogous to the RLC circuit – a block–spring system moving in a viscous medium.

The log decrement is determined from the ratio of the voltages of successive maxima of the damped oscillatory signal. This measurement is taken from the oscilloscope display, as shown in the Fig. 4. The figure shows the damped signal for two different values of resistance for fixed value of capacitance. The arrows indicate the first and second maxima.

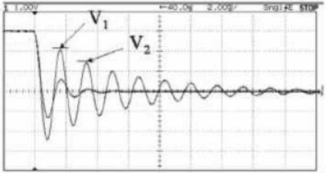

Fig. 4. Typical oscilloscope trace showing log decrement measurement

---

unloaded Q. In this case the L-C circuit under test “sees” the same Q as we have measured, (if it could look at its environment by looking towards the source and detector).

Such is not the case in methods 3 and 4. In method 3 the L-C circuit will typically “see” a 50 ohm source and a 50 ohm detector that are effectively in parallel. This adds 25 ohm in series with the ESR of the L-C circuit, and reduces the Q that it sees. This loaded Q sets the selectivity of the notch filter created by the circuit.

In method 4, the L-C “sees” the SWR analyzer internal impedance, say 50 ohm. Remember that the Rp value is transformed to 50 ohm at the analyzer, and effectively is in parallel with the analyzer’s internal impedance. This means that the actual Q factor seen by the L-C circuit is reduced by half. This value is the loaded Q of the L-C circuit. In this case the coupling factor equals 1.5

Now consider a 50 ohm dipole antenna. The series R-L-C model may be applied to a resonant dipole antenna, which presents approximately 50 ohm at the feed point. When the dipole is fed by a low loss transmission line the SWR meter connected at the transmitter will measure the antenna unloaded Q at an SWR = 2.62 as calculated from equation 3: Q = f0 / BW. Note that the spreadsheet given in Note 4 will calculate the dipole Q factor under these conditions.

When the antenna is fed by a 50 ohm source, its effective bandwidth will double, since the total resistance seen by the dipole is now the radiation resistance plus the transmitter output resistance.

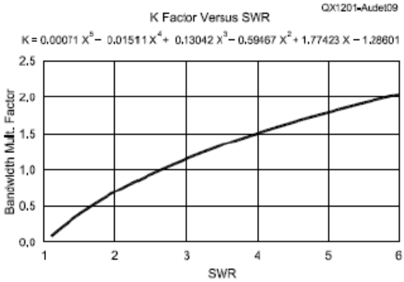

Figure 9 — This graph shows the K factor versus SWR. At SWR = 2.62 the correction factor K equals 1 while at SWR = 5.83 the K factor is 2.

Here we still have the loaded Q = unloaded Q / 2. This assumes that the transmitter output impedance and the feed line are 50 ohm. The Q derived from the bandwidth at SWR points of 2.62 gives the unloaded Q value, independently of the transmitter output impedance.

In the general case, the complex impedance of the transmitter reflected at the antenna will modify its effective bandwidth and its actual resonant frequency. Note that the SWR meter connected at the transmitter will not show this effect since it can only measure the unloaded Q of the dipole. Also, the bandwidth of the matching circuits at the transmitter will affect the effective impedance seen by the antenna and modify its loaded Q and bandwidth.

is a circuit damping constant

The equation **** describes a sinusoidal oscillation with an exponentially decaying amplitude $Qe^{-\frac{Rt}{2L}}$.

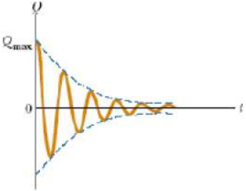

Fig. 2 Charge versus time for the damped RLC circuit.

The RLC circuit is analogous to the damped harmonic oscillator illustrated in Fig. 3 and described by the equation:

$$m\frac{d^2x}{dt^2}+b\frac{dx}{dt}+kx=0$$

Q corresponds to the position x of the block at any instant, L to the mass m of the block, R to the damping coefficient b, and C to 1/k, where k is the force constant of the spring.

$$\frac{dU}{dt} = Li\frac{di}{dt} + \frac{q}{C}\frac{dq}{dt} = -i^2 R$$

$$i = \frac{dq}{dt} \text{ and } \frac{di}{dt} = \frac{d^2 q}{dt^2}$$

$$L\frac{d^2 q}{dt^2} + R\frac{dq}{dt} + \frac{1}{C}q = 0$$

$$\frac{d^2 q}{dt^2} + 2\frac{R}{2L}\frac{dq}{dt} + \frac{1}{LC}q = 0$$

$$\frac{R}{2L} = \beta, \qquad \frac{1}{LC} = \omega_0^2$$

$$\frac{d^2 q}{dt^2} + 2\beta\frac{dq}{dt} + \omega_0^2 q = 0$$ ***

The solution to this differential equation for damped oscillations in an RLC circuit is:

$$q = Qe^{-\frac{Rt}{2L}}\cos(\omega t + \varphi)$$ ****

where:

$$\omega = \sqrt{\omega_0^{\,2} - \left(\frac{R}{2L}\right)^2}$$

is the angular frequency of the damped oscillations,

$$\omega_0 = \frac{1}{\sqrt{LC}}$$

is the angular frequency of the undamped oscillations.

$$\omega = \sqrt{\frac{1}{LC} - \left(\frac{R}{2L}\right)^2}$$

$$\beta = \frac{R}{2L}$$

One way to measure the effective bandwidth of the dipole might be to insert an RF ammeter in series with one dipole leg. Find the frequencies where the current is reduced by ~ 30% and compute the effective bandwidth this way. In the receive mode the dipole antenna will also exhibit the same loaded Q = unloaded Q / 2 if the receiver impedance is 50 ohm. Your antenna effective bandwidth may be twice as large as you really thought!

Summary of the Four Methods Presented in this Article

1 – Classical Q Meter. See Figure 1. This shows a set-up as used by the HP / Agilent model HP 4342A.

This technique uses a transmission method that requires a very low impedance source and very high impedance detector, which are not easy to realize.

Set the frequency and adjust the reference capacitor for resonance.

The measurement approximates the unloaded Q. Corrections are difficult to apply.

You don’t have to know the L-C values.

2 – Transmission Method Using Coupling. See Figure 2. This technique requires a source and a voltmeter.

Find the –3 dB transmission bandwidth points. The measurement requires two low value, high Q coupling capacitors.

It measures the loaded Q as used in the test circuit.

You need to correct the loaded Q value for attenuation to find the unloaded Q, if the attenuation is less than 30 dB.

The accuracy of the Q measurement remains somewhat dependant upon the Q factor of the coupling capacitors. Refer to Figure 2. With 1 pF coupling capacitors having a Q of 1000, the error on Q was – 1.4%.

The L or C values are not required.

3 – Shunt mode transmission method with LC connected in series. See Figure 4.

This method requires a source and a selective voltmeter to prevent source harmonics from affecting the measurement. Compute the ESR from the minimum attenuation measured at resonance.

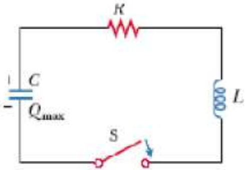
The L or C values are required to compute the Q value.

The author’s spreadsheet computes the series/parallel R-L-C values from 3 attenuation measurements. This technique is also useful for crystal measurements.

This is potentially the most accurate method, if the attenuation is measured with high accuracy using a vector network analyzer (VNA).

4 – Reflection measurement using an SWR analyzer. See Figures 7 and 8.

oscillations of charge, current and potential difference continuously decrease in amplitude, and the oscillations are said to be damped.



Let's write the equation for the total electromagnetic energy U in the circuit at any instant. As we know the resistance doesn't store electromagnetic energy, so we have:

$$U = U_B + U_E = \frac{Li^2}{2} + \frac{q^2}{2C} \quad *$$

This total energy decreases because energy is transferred to thermal energy. The rate of this
transfer is:

$$\frac{dU}{dt} = -i^2 R \quad **$$

where the minus sign indicates that U decreases.
By differentiating * with respect to time and then substituting the results in ** we obtain:

Damped oscillations in RLC circuits

by Barbara Dziurdzia
AGH University of Science and Technology in Cracow
http://home.agh.edu.pl/~lyson/downloads/Manual_8.pdf

1. Goal

To observe damped oscillations in the RLC circuit and measure the amplitude, period, angular frequency, damping constant and log decrement of damped oscillatory signals. To find the critical resistance for which the critical damping occurs.

2. What to learn?

Transfer of energy in LC circuit. The electrical-mechanical analogy. Differential equation describing damped simple harmonic motion in the RLC circuit.. Solution of this equation. Angular frequency of the damped oscillator. Damping constant. Angular frequency of the undamped oscillator. Forced oscillations and resonance. Kirchhoff's rules. Log decrement of damped oscillatory signals. Critical damping. How does the oscilloscope work?

3. Background

A circuit consisting of an inductor, a capacitor, and a resistor connected in series (Fig. 1) is called an RLC circuit. The resistance of the resistor R represents all of the resistance in the circuit. .With the resistance R present, the total electromagnetic energy U of the circuit (the sum of the electrical energy and magnetic energy) decreases with time because some portion of this energy is transferred to thermal energy in the resistance. Because of this loss of energy, the

---

This technique requires a matching capacitor or variable link coupling. There will be a slight interaction between the matching components and the main tuning capacitor.

Adjust two variable capacitors or vary link coupling to obtain an SWR of approximately 1:1

Toroidal inductors are difficult to test with variable link coupling. Use the capacitive divider method instead. With link coupling, keep the link close to the grounded end of the coil, to minimize capacitive coupling. In general air wound coils are more delicate to test since they are sensitive to their environment.

The L and C values are not required.

Offset the frequency to have an SWR increase. Note the frequency and SWR.

The author’s spreadsheet computes the unloaded Q factor directly.

This technique requires the least equipment of any of the methods.

Best accuracy is obtained with a link coil or a variable capacitive divider.

While all four methods do not require phase or complex impedance measurements, method 4 only requires an SWR analyzer. The accuracy of the SWR analyzer method has been validated from RF Simulations and by actual measurements.

Since this method relies on SWR measurements, the accuracy of the measuring instrument should be verified. The SWR = 2 point may easily verified by placing two accurate (≤ 1%) 50 ohm resistors in parallel at the analyzer output using a tee connector. Note the reading obtained at the frequency of interest and compute the SWR offset from the ideal value of 2.00. Then perform the Q measurements around this same SWR value, possibly above and below the resonant frequency and average the Q results.

To compensate for inaccuracies in determining the frequency (f0) of 1:1 SWR, it is recommended that you perform the Q measurement at two frequencies above and below the f0, as done in the spreadsheet provided in Note 4.

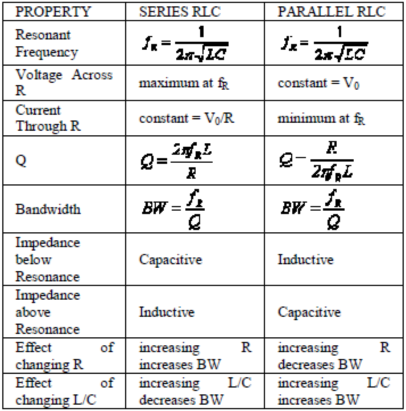
Note 5 covers other methods of measuring Q using a vector network analyzer, mostly suitable for use at microwave frequencies.

Jacques Audet, VE2AZX, became interested in radio at the age of 14, after playing with crystal radio sets and repairing old receivers. At 17, he obtained his first ham license, and in 1967 he obtained his B Sc degree in electrical engineering from Laval University. He then worked in engineering functions at Nortel Networks, where he retired in 2000. He worked mostly in test engineering on a number of products and components operating from dc to light-wave frequencies.

His areas of interest are in RF simulations, filters, duplexers, antennas and using computers to develop new test techniques in measurement and data processing.

Notes

Let us summarize what we have learned about parallel and series RLC circuits:



PROPERTY	SERIES RLC	PARALLEL RLC
Resonant Frequency	$f_R = \frac{1}{2\pi\sqrt{LC}}$	$f_R = \frac{1}{2\pi\sqrt{LC}}$
Voltage Across R	maximum at f_R	constant = V_0
Current Through R	constant = V_0/R	minimum at f_R
Q	$Q = \frac{2\pi f_R L}{R}$	$Q = \frac{R}{2\pi f_R L}$
Bandwidth	$BW = \frac{f_R}{Q}$	$BW = \frac{f_R}{Q}$
Impedance below Resonance	Capacitive	Inductive
Impedance above Resonance	Inductive	Capacitive
Effect of changing R	increasing R increases BW	increasing R decreases BW
Effect of changing L/C	increasing L/C decreases BW	increasing L/C increases BW

frequency at which the current increases to 141.4% of the minimum. The 141.4% current points were chosen because they correspond to a doubling of the power.

$BW = f_U - f_L$

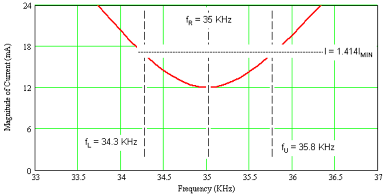
Q is defined as:

$$Q = \frac{R}{2\pi f_R L}$$

Bandwidth and Q are also related as follows:

$$BW = \frac{f_R}{Q}$$

The graph below illustrates the definition of BW.



The bandwidth is 35.8 - 34.3 = 1.5 KHz. Now we can determine Q:

$$Q = \frac{f_R}{BW} = \frac{35 KHz}{1.5 KHz} = 23.3$$

As a check, we can use our other definition to determine Q:

$$Q = \frac{R}{2\pi f_R L} = \frac{1000}{42.89} = 23.3$$

As one would expect, both results agree.

Appendix 1

In the SWR analyzer method, the equivalent parallel resistance RP of the L-C circuit is transformed to 50 ohm to give 1:1 SWR at resonance by using an adjustable link coupling or a variable capacitive divider. As the frequency is varied around resonance, it may be set at two frequencies where the absolute value of the reactance, X, is equal to RP.

Abs(X) = RP

Normalizing these impedances gives impedances of 1 for RP and j for X. Since these are in parallel, the resulting impedance, Z, will be:

$$Z = \frac{1 \times j}{1 + j} = 0.5 + 0.5j$$ [Eq A-1]

Taking the absolute value of Z we get Z = 0.707. This is the –3 dB point, since this value is 3 dB below the initial value of 1. The complex reflection coefficient is:

$$\rho = \frac{(0.5+0.5j)-1}{(0.5+0.5j)+1} = -0.2+0.4j$$ [Eq A-2]

The absolute value of the reflection coefficient $|\rho|$ is 0.447. The return loss RL in dB is given by:

RL = –20 log $|\rho|$ = 6.99 [Eq A-3]

The corresponding SWR is given as:

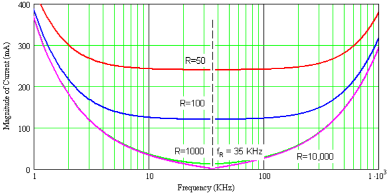
$$SWR = \frac{1+\rho}{1-\rho} = 2.62$$ [Eq A-4]

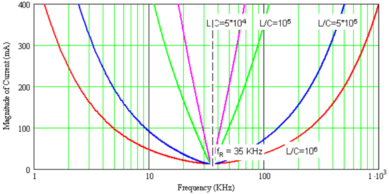
At the – 3 dB points, the bandwidth (BW) is related to the unloaded Q factor as follows:

$$Q_U = \frac{f_0}{BW}$$

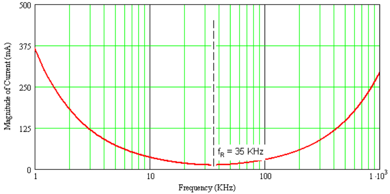
Therefore, measuring the bandwidth, BW, at SWR = 2.62 allows us to compute the unloaded Q (QU) of the circuit. So far, we need three measurement points. One point at frequency f0 that gives 1:1 SWR and two points at fL and fH below and

The shape of the band-stop response of a parallel RLC circuit depends on the value of R and L/C as shown in the next graphs.

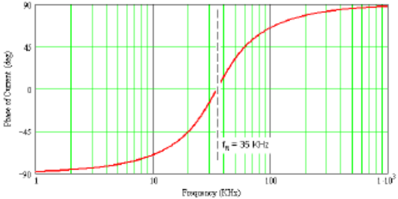




Note that the band-stop characteristic becomes narrower as the value of R increases. This the opposite of what we saw in the series RLC circuit. The response also becomes narrower as the L/C ratio decreases, which again is the opposite of what we saw in the series RLC circuit. We can summarize this behavior by using two additional parameters, Q and the bandwidth, BW. We define bandwidth for parallel RLC circuits, as the difference in frequency between the upper frequency at which the current increases to 141.4% of the maximum and the lower frequencies near the resonant frequency, while allowing others to pass.



The graph below shows the variation in phase shift of the current through the parallel RLC circuit.



Notice that the current has no phase shift at the resonant frequency. At frequencies below the resonant frequency the current lags the applied voltage and the circuit acts like an inductor. At frequencies above resonance, the current leads the applied voltage and the circuit acts like a capacitor.

---

above resonance that give an SWR of 2.62. The last two points are symmetrical around f0, so only one is measured as f = fH.

Since fL × fH = f0 [Eq A-5]

The other frequency fX is assumed to be at:

$$f_X = \frac{f_0^2}{f_H} = \frac{f_0^2}{f}$$ [Eq A-6]

The bandwidth BW1 may now be calculated:

$$BW_1 = f - f_X = f - \frac{f_0^2}{f}$$ [Eq A-7]

Since we want to be able to measure at any SWR value, we need to add a correction factor, K, resulting from the use of bandwidth BW1.

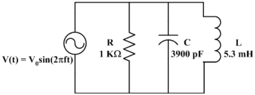
$$Q_U = \frac{K\, f_0}{BW_1}$$ [Eq A-8]

The correction factor, K, is the bandwidth multiplication factor. It is a function of the SWR. I derived K using Mathcad™ numerical calculations and then normalized the value. I used a fifth order polynomial to fit the computed data. See Figure 9. Note 4 gives the Mathcad™ and Adobe PDF files that I used, as well as more details on the derivations. The complete equation as used in my spreadsheet for the unloaded Q factor becomes:

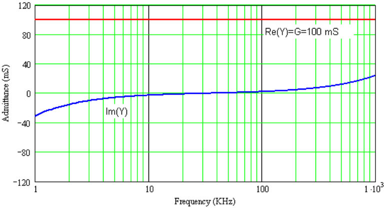
$$Q_0 = \frac{f_0 \cdot \left(1.77423 \cdot SWR - 0.59467 \cdot SWR^2 + 0.13042 \cdot SWR^3 - 0.0151 \cdot SWR^4 + 0.00071 \cdot SWR^5 - 1.28601\right)}{\left| f - \frac{f_0^2}{f} \right|}$$

[Eq A-9]

Let us look at a specific parallel RLC circuit and explore its behavior.



The graph below shows the variation of the admittance of this parallel RLC circuit with frequency.



We can compute the resonant frequency from the component values:

$$f_0 = \frac{1}{2\pi\sqrt{LC}} = \frac{0.159}{\sqrt{(5.3*10^{-3})(3900*10^{-12})}} = \frac{0.159}{\sqrt{2.067*10^{-11}}} = \frac{0.159}{4.546*10^{-6}} = 35.0\ \text{KHz}$$

Note that this parallel RLC circuit has the same resonant frequency as the series RLC circuit examined earlier. In general, the resonant frequency depends only on L and C and not whether they are connected in parallel or series.

The next graph shows the variation in the current through the parallel RLC circuit. Notice that the current is a minimum at the resonant frequency. This is an example of a "band-stop" circuit response. A parallel RLC circuit can be used to block

Inductive susceptance:

$$B_L = \frac{-j}{2\pi fL}$$

Capacitive susceptance:

$$B_C = j2\pi fC$$

And of course, conductance is defined as follows:

$$G = \frac{1}{R}$$

By analyzing the parallel RLC circuit using admittance, we will be able to use nearly all of what we have already learned about series RLC circuits. Admittances in parallel add, just like impedances in series. We can immediately write the equation for the admittance of the parallel RLC circuit by adding the admittances of the three components:

$$Y = G + B_C + B_L = \frac{1}{R} + j2\pi fC - \frac{j}{2\pi fL}$$

This can be simplified to the following expression:

$$Y = G - j2\pi fC\left(1 - \frac{1}{4\pi^2 f^2 LC}\right)$$

The imaginary part of the admittance vanishes when:

$$4\pi^2 f^2 LC = 1$$

We define the frequency at which this occurs to be the resonant frequency, given by the following formula:

$$f_R = \frac{1}{2\pi\sqrt{LC}}$$

The equation for the admittance of the parallel RLC circuit can be simplified further:

$$Y = G + j2\pi fC\left(1 - \left(\frac{f_R}{f}\right)^2\right)$$

Experiments with Coils and Q-Measurement

Wes Hayward, w7zoi,
October, 2007 (Updates 01Dec07, 08Dec08.)
http://web.archive.org/web/20101226143919/http://w7zoi.net/coilq.pdf

I recently became interested in building a “Zero Power Receiver (ZPR)”, a circuit that would receive the AM broadcast band while using no external power. There would be no batteries or other sources of energy. This is, of course, the classic crystal set that most of us built in our youth. But building a contemporary ZPR is a different exercise than it was for those youthful interludes. The main difference is the presence of considerably more science in the process than we used in the construction of that first crystal set. There are some really wonderful web sites out there that present much of this work. Another difference is that the modern ZPR may not even use a “crystal,” or diode detector. Instead, it may use a field effect transistor. The most recent published design that I know about was presented by Bob Culter, N7FKI, in QST for January, 2007. Bob used a new zero threshold MOSFET in his ZPR.

The w7zoi amateur radio set up and listening post, September 30, 2007. A ZPR resides on top of the Icom R75 communications receiver.

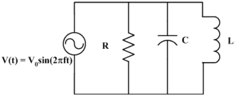
Those interested in finding out more about the modern crystal set should go to the world wide web with a good search engine such as Google. The first place to go is the Birmingham, Alabama Crystal Radio Group. They have a collection of links listed on their web page that will get you to many of the other really good sites. Birmingham really is the center for much of this activity, probably the result of some local activity that grew into something greater. These guys are to be commended for work that gets a lot of us thinking and trying something different. Be sure to look at their photo collection and at the results from their contests.

I'll not spend too much more space with further discussion of crystal sets here. This note is related to some of the measurement methods that I have used for Q measurements. But there is one piece of data that I do want to emphasize, for this was the thing that got my attention: The gang from Birmingham hold an annual listening contest that goes on for

The voltage response of the series RLC circuit can be completely characterized by its resonant frequency, f_R, and Q or the bandwidth, BW.

Parallel RLC Circuits

A parallel RLC circuit, also called a tank circuit, is one in which R, L, and C are in parallel, as shown below.



Much of what we just learned about series RLC circuits will carry over into parallel RLC circuits. Before we begin we need to define a new concept known as admittance. Admittance is the reciprocal of impedance and its symbol is Y:

$$Z = \frac{1}{Y}$$

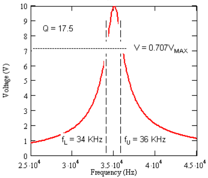
The unit of admittance is the Siemens (S). 1 Siemens = 1 ohm^{-1}. Like impedance, admittance is a complex number, consisting of a real part and an imaginary part. The real part is called conductance, G, and the imaginary part is called susceptance, B:

$Y = G+jB$

Admittance is very handy when analyzing parallel circuits because the total admittance of a group of components in parallel is simply the sum of their individual admittances. Our formulas for inductive and capacitive reactance can be converted to formulas for susceptance:

Another way to look at this is to say that the Q is the ratio of the reactance of the inductor to the resistance, at resonance. High Q RLC circuits have a very sharp response. Low Q RLC circuits have a broad response.

We have talked about the bandwidth of a circuit without defining exactly what it is. Now we will define it.



Referring to the figure above, bandwidth (BW) is defined as the difference in frequency between the upper frequency at which the voltage drops to 70.7% of the maximum and the lower frequency at which the voltage drops to 70.7% of the maximum. The 70.7% voltage points were chosen because they correspond to a power decrease of 50%. Thus:

$BW = f_U - f_L$

Bandwidth and Q are also related as follows:

$$BW = \frac{f_R}{Q}$$

In the graph above, Q = 17.5, and f_R = 35 KHz. The bandwidth is:

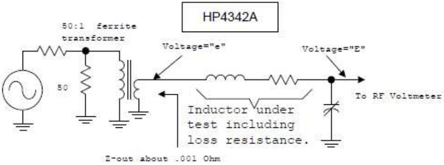
$$BW = \frac{35000}{17.5} = 2000\,Hz = 2\,KHz$$

over a week in the dead of winter. They then collect the logs to see who is hearing the good stuff. The folks who win are not just listening to the local stations in their area. Rather, they log stations from hundreds, and even thousands of miles away! A winning log may well contain over a hundred stations. One recent winner was from Hawaii.

Q-Measurement using a Q-Meter

The basic ZPR has at least one tuned circuit that serves to tune the receiver to a desired station. Most of the receivers that are built by those who listen to far distant broadcasts will have several. While there is considerable lore on the web that present an algorithm for coil construction, this does not provide the numbers we need for design. If we are to really be able to analyze the circuits that we build, even in a circuit as primitive as a crystal receiver, we must do measurements on key components to characterize, and hence, model them. We must have resonator Q.

Shown below is the basic topology of a Q-Meter, the HP-4342A.



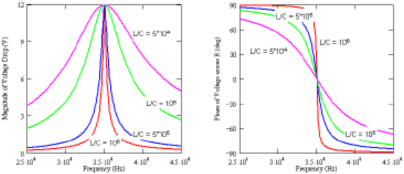
A relatively modern Q Meter. This particular model is perhaps the last of its kind.

This instrument has a built in signal generator (22 kHz up to 70 MHz) that supplies energy to a ferrite transformer with an extremely low output impedance, around one milliohm. The output has a magnitude "e". This level is maintained with a detector and feedback loop. The signal is then applied to the inductor under test, which is attached to terminals on top of the instrument. The inductor is tuned to resonance with a high quality, calibrated, built-in variable capacitor. The voltage across the capacitor is measured with a very high impedance RF voltmeter. The value of this voltage, E, is then directly related to Q. The lower the net series resistance, the higher E will be.

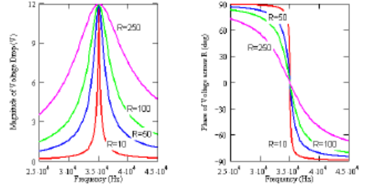
Some amateur experimenters have built homebrew Q meters using the HP scheme. Calibration may be a challenge, but the basic concepts are fundamental and would form a sound basis for experimental efforts. I might be tempted to try some of the very wideband op-amps that are available today as a way to generate the ultra low output impedance drive.

A modern measurement performed in industry or at an institution of higher learning will probably be done with a network analyzer. We will not go into any detail here, for that will take us far from our immediate goals. However, we should state that it is now quite possible for the amateur experimenter to build his or her own network analyzer. Some of the "antenna analyzers" now on the market edge in this direction. A network analyzer was described a few years ago in QEX. In my opinion though, the finest example of a homebrew analyzer is that presented by Paul Kiciak, N2PK. Paul’s vector (meaning that it gives impedance magnitude and angle, or real + imaginary) is found on the web at http://n2pk.com/ and offers measurements to 60 MHz with a 100 dB dynamic range.

Although there are many combinations of L and C that will give the same resonant frequency, the shape of the curve representing VR depends on the L/C ratio as shown below.



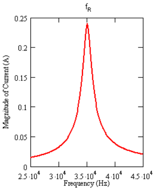
As the L/C ratio increases, the response becomes sharper.
The value of series resistance, R, also affects the shape of the V_R curve as shown below:



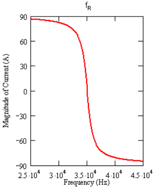
As the series resistance gets larger, the voltage curve gets broader.

In order to make sense of all these possibilities, it is necessary to introduce some new parameters. This first is Q, the quality factor of the series RLC circuit. Q is defined as:

$$Q = \frac{2\pi f_R L}{R}$$



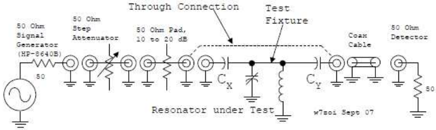
The magnitude of the current is maximum at the resonant frequency and $|I_{max}| = V_0/R = 12/50 = 240$ mA. This type of circuit behavior is called a band-pass response. If a complex signal containing many different frequencies was applied to the series RLC circuit and the output taken across R, the output would contain mostly frequencies near the resonant frequency. The next graph shows the phase of the current through the series resonant circuit.



At frequencies below the resonant frequency, the current leads the voltage, which is characteristic of an RC circuit. At frequencies above resonance, the current lags the voltage, and the series RLC circuit looks like a series RL circuit. At resonance, the current and voltage are in phase.

A Still Viable Classic Q Measurement

In earlier times when a network analyzer was not as available to the experimenter as it is today, resonator (another term for tuned circuit) Q was measured by examining the bandwidth of the circuit. The Q is then just the ratio of the center frequency to the bandwidth. A system for this is shown below.



A classic scheme for measurement of Q. CX and CY are adjusted for high loss. See text.

The use of this method is very general and is not restricted in frequency. I've used it to evaluate low frequency inductors used in audio filters as well as components for microwave filters. Like most RF measurements, a 50 Ohm system is used for both a driving RF source and for the load. It is vital to have digital frequency readout. A counter can be attached to an analog calibrated generator. The generator is followed by a step attenuator. This can be homebrew and is trivial for measurements up through the HF spectrum. All we will need for this measurement is a 3 dB step. However, it should be fairly accurate. (See EMRFD chapter 7 for info on attenuators.) The step attenuator is followed by a fixed pad to establish a Z0 environment. This pad should ideally be right next to the following test fixture that contains the tuned circuit we are measuring. The test fixture output is routed to a 50

Ohm detector. This can be a power meter, a spectrum analyzer (my usual choice), or a 50 Ohm terminated oscilloscope. If the ‘scope option is picked, the termination should be at the input to the oscilloscope and not out at the test fixture end of the connecting cable. With a 50 Ohm terminator at the ‘scope, the test fixture will see 50 Ohms at all frequencies, no matter what the cable length might be.

The first step in use is to put a jumper (usually a BNC barrel) from the fixed pad to the cable leading to the detector, shown as a dotted line in the figure above. The level in the detector is then noted. If you are using a ‘scope, calculate the power in dBm. Power in dBm is usually read directly if you are using a power meter or spectrum analyzer. Then connect the test fixture with its tuned circuit and tune the signal generator and/or variable capacitor to obtain a detector peak. The peak response will always be less than was seen with the "through" connection. That direct connection represented a matched impedance case where all of the available power from the signal generator is transferred to the detector.

It’s now time to extract some numbers. Set the step attenuator to 3 dB and then tune the generator for a peak in output response. Peak the resonator capacitor if necessary. Note the frequency for this peak response. Now comes an important part of the procedure that is easy to bypass. Note the power seen in the detector and record it in your notebook. It should be at least 30 dB below the maximum available power that we measured with the through connection. Let’s assume, for the moment, that it is.

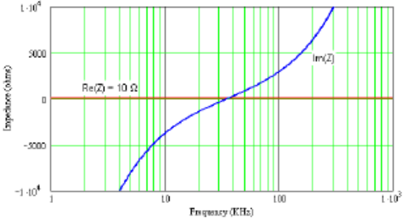
We now carefully note the detector level. If we are using a spectrum analyzer or an oscilloscope, we adjust the signal generator amplitude just a bit so the trace is right on a cursor

---

$$Z = R + j2\pi fL\left(1-\left(\frac{f_r}{f}\right)^2\right) = 50 + j6.2832f*5.3*10^{-3}\left(1-\left(\frac{3.5*10^4}{f}\right)^2\right)$$

$$= 50 + j\left(0.0330f - \frac{40.79*10^6}{f}\right)$$

The graph below shows how Z varies with frequency:



We can find the current through the series RLC circuit by using Ohm's Law:

$$I = \frac{V}{Z} = \frac{12}{50 + j\left(0.0330f - \frac{40.79*10^6}{f}\right)}$$

rather than simplify this ugly expression further, we will graph the current as a function of frequency:

called the resonant frequency. It is possible to derive an equation for the resonant frequency in terms of L and C from the condition $4p_2f_2LC = 1$:

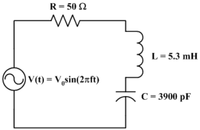
$$f_R = \frac{1}{2\pi\sqrt{LC}}$$

where:
f_R = resonant frequency (Hz)
L = inductance (H)
C = capacitance (F)

The resonant frequency depends on the product of L and C, not the individual values, and is independent of R. We can use the formula for the resonant frequency to simplify our equation for the impedance of the series RLC circuit as follows:

$$Z = R + j2\pi fL\left(1 - \left(\frac{f_R}{f}\right)^2\right)$$

Let us examine the behavior of a series RLC circuit in more detail by studying the circuit shown below:



.

We can immediately calculate the resonant frequency:

$$f_R = \frac{1}{2\pi\sqrt{LC}} = \frac{0.159}{\sqrt{(5.3*10^{-3})(3900*10^{-12})}} = \frac{0.159}{\sqrt{2.067*10^{-11}}} = \frac{0.159}{4.546*10^{-6}} = 35.0\,\mathrm{KHz}$$

We can substitute in values for fR, R, and L to get the total impedance:

line on the display. An adjustment of oscilloscope vertical position may also be used for this.

Next, remove the previously added 3 dB attenuation. This will cause the response to increase, doubling the detector power. (An oscilloscope voltage response will go up by a factor of 1.41.) Now carefully tune the signal generator to a higher frequency until the response has dropped to produce exactly the same level that we had at the peak. Record this upper frequency in your notebook. Next, the generator is tuned back toward and through the peak until the previously noted amplitude is again obtained. This occurs at a lower bandwidth edge. The difference between the upper and the lower frequencies is the resonator bandwidth. The Q is then the ratio.

$$\mathrm{BW} = \mathbf{F}_{\mathbf{upper}} - \mathbf{F}_{\mathbf{lower}}$$

$$\mathrm{Q} = \frac{\mathbf{F}_{\mathbf{center}}}{\mathbf{BW}}$$

Consider now the earlier assumption that there was at least 30 dB loss through the test fixture containing the resonator and connecting capacitors. This loss relates to the choice of CX and CY shown in the schematic diagram for the classic measurement. First, it is important that the values be approximately the same value. This guarantees that any loading by the Z0 source will equal the loading by the Z0 detector. If CY was much larger that CX, for example, we could have a situation where the detector would severely load the resonator, but we could still have 30 dB or more attenuation. So make the two loads about the same. A loss of 30 dB or more means that the dominant loss mechanism is the loss within the tuned circuit and not the loss related to loading by the source or detector.

The way we adjust the loading at the ends of this single resonator filter is by picking CX and CY. The values we use will depend upon the capacitor in the resonator. If, for example, we have a resonator capacitance of 300 pF, we can probably get our 30 dB loss with values of perhaps 3 pF for CX and CY. I would probably grab 1 pF for each part from the junk box. Exact details will change as we go to much higher frequency. The concepts are the same though. For example, when evaluating a VHF helical resonator, or similar LC-like structure, we might have nothing more than a pair of coaxial connectors mounted in the resonator wall. The normal center pins from the connectors may well be enough coupling. Indeed, I have encountered situations where it was necessary to recess the connectors in the wall so that the center wires are partially hidden. Good measurement results are guaranteed if the 30 dB rule is maintained and symmetrical loading is achieved. If the Q exceeds 500 or 1000, it may be useful to go to loss greater than 30 dB. Alternatively, a correction can be applied. See page 58 of Introduction to RF Design (ARRL, 1994.)

Some of these details are not intuitive. A good way to build some intuition is to do simulations in LT Spice, which is free from Linear Technology on the web. (Bravo for LT—many thanks!) You can then "build" inductors in software, with appropriate series resistance. Then sweep the filter and see if you get the right Q by observing the 3 dB points.

The procedure outlined is general and applies to any frequency. The use of low impedances allows extreme flexibility. Some folks have measured Q with a similar approach where a small probe coil is driven by the generator and is placed near the resonator being studied. An oscilloscope

This expression in more complex than those derived in earlier sections for the series RL and RC circuits and as a result, the behavior of a series RLC circuit is much more interesting. Let us consider several interesting cases:

Case 1: f <<1.

If the frequency is very close to 0 Hz, the j2pfL term in the original expression for Z is approximately 0. In this case the impedance of the parallel RLC circuit can be approximated by the following equation

$$Z \approx R - \frac{j}{2\pi fC}$$

At very low frequencies, the series RLC circuit behaves like a series RC circuit.

Case 2: f >> 1

When the frequency is very large, the -j/(2pfC) term in the original expression for Z is approximately 0. In this case the impedance of the series RLC circuit can be approximated by the following equation

$$Z \approx R + j2\pi fL$$

At very high frequencies, the series RLC circuit behaves like a series RL circuit.

Case 3: $4p_{2}f_{2}LC = 1$

When this condition occurs, the imaginary part of Z is zero. The impedance of the series RLC circuit is real and is equal to the resistance:

Z = R

The circuit behaves as if the inductor and capacitor were not present. The negative reactance of the capacitor and positive reactance of the inductor add up to 0, creating a condition is known as resonance, which occurs at a specific frequency

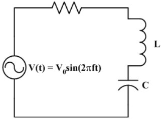
RLC Circuits

An RLC circuit contains resistors, inductors and capacitors. In this section we shall look at the two simplest RLC circuits, the series RLC circuit and the parallel RLC circuit.

Series RLC Circuits



Since the resistor inductor and capacitor are in series, the total impedance of the series RLC circuit is the sum of the individual impedances:

$Z = R + X_L + X_C$

After substitution of the formulas for X_L and X_C one gets the following expression for Z in terms of f, R, L and C:

$$Z = R + j2\pi fL - \left(\frac{-j}{2\pi fC}\right)$$

This can be simplified by combining the imaginary terms:

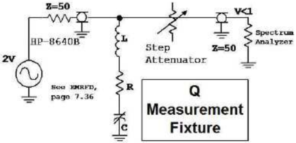
$$Z = R + j2\pi fL\left(1 - \frac{1}{4\pi^2 f^2 LC}\right)$$

---

is then used with a 10X probe and a small value series capacitor as a detector. The series capacitor is important, for even with a 10X probe, the impedance at RF might still excessively load the resonator. It is important to keep the source probe inductor well away from the coil. The concepts are the same and can all be modeled with appropriate calculations.

The EMRFD Q-Measurement Scheme

An alternative scheme is presented in Experimental Methods in RF Design (ARRL, 2003) in Chapter 7, page 7.36. In this method, a tuned circuit containing the inductor to be measured is configured as a series resonator and is then connected as a shunt element. The basic scheme is shown below.



Alternative Q measurement scheme.

A steady strong output is seen in the detector as the signal generator is tuned. As resonance is reached, the output dips down. The reactance of the inductor is cancelled by that of the capacitor exactly at resonance, leaving nothing but the loss resistance, R, to attenuate the signal reaching the detector. The higher the Q, the greater the dip will become. A more detailed diagram is shown below.

Alternative Q measurement system. See text for explanation.

The procedure for using this method begins with setting the signal generator to the desired frequency. The level is noted in the spectrum analyzer. A power meter or 50 Ohm terminated oscilloscope can also be used if the signal generator is known to be low in harmonic content. (Not all signal generators fulfill this criterion though, so be careful. The HP-8640B that I use has very low harmonic output. If you are concerned, use a low pass filter with the generator.) The capacitor in the test fixture is then tuned to produce a dip. Use the highest possible amplitude resolution you have in your detector. I go to a 2 dB/division mode with my spectrum analyzer. After an initial dip has been set with the capacitor, use the signal generator to select the lowest dip response. Then use an amplitude control on either the detector or generator to move the observed signal to a cursor line.

Record the signal generator frequency. Then take the test fixture out of the system, realized in my setup by substituting a BNC barrel for the test fixture. The signal will increase at the detector. Increase the attenuation in the step attenuator until the same response at the cursor line is observed. This will provide an attenuation or dip value. Interpolate as needed to

EE. Bucher, 1919, "Wireless Experimenter’s Manual", Wireless Press, New York.

Wes Hayward, W7ZOI, Experiments with Coils and Q-Measurement, October, 2007 (Updates 01Dec07, 08Dec08. http://web.archive.org/web/20101226143919/http://w7zoi.net/coilq.pdf

Steve Ratzlaff, AA7U kindly made detail measurements on the Q of the capacitors and coils used in this report.

Dick Kleijer , 2013, Measuring the Q of LC Circuits,
http://www.crystal-radio.eu/enqmeting.htm

Barbara Dziurdzia, 2013, Damped oscillations in RLC circuits, AGH University of Science and Technology in Cracow,
http://home.agh.edu.pl/~lyson/downloads/Manual_8.pdf

Rice University EE., RLC Circuits,
http://www.owlnet.rice.edu/~phys102/Lab/RLC_circuits.pdf

Durham University EE., Oscillations and Resonances in LRC Circuits,
http://level1.physics.dur.ac.uk/projects/script/lcr.pdf

This is slightly low to Steve's measured 240Q. I am of the opinion that the original tank measurement may have been a bit on the low side. Still, again the results are within the ballpark and the technique works if you have a good measure on the Q of the capacitor used in your tank. Alternatively, starting with a known coil Q, the technique will work equally well to determine the Q of an unknown capacitor.

Conclusion:

If you have access to, or own a digital oscilloscope, or have been hankering to purchase one, then the time may be now. The analytical method presented above is simple in practice and robust in theory. I would also say that, by working with your wave forms, you learn to recognize your data and soon get a good "feel" for what is good and what is not. The technique also produces, should you wish, an auditable report of the wave and analysis. It is hard to argue against the results with the waveform sitting there staring right at you!

Measuring your coil Q should not be difficult.

A copy of the evaluation spreadsheet in xls format can be found here CoilQbyDecrement_kjs.xls

obtain data within 0.1 or 0.2 dB. Record this value in the notebook with the previous center frequency.

Finally, unsolder the inductor from the circuit at the point marked with the large X in the figure. Then attach a capacitance measuring meter to measure the C value. I used one of the AADE L/C meters. (Just Google AADE on the web.) The C value is recorded. The F and C data allows calculation of the effective inductance. The inductor equivalent series resistance can then be calculated from the attenuation, which then leads directly to Q. The equations are included in the EMRFD presentation.

An advantage of this scheme is that the Q value is directly related to the attenuation value, which is relatively easy to determine with an accurate step attenuator. (I use a surplus HP-355C and HP-355D combination.) The detector operates directly on a null point rather than along the slope of an attenuation function where frequency drift can complicate the results. But the method is sensitive to the driving and load impedance at the test fixture. Values other than 50 Ohms will compromise results It may even be important to actually use 50 Ohm cables; the 52 Ohms of RG-58 might not be close enough. A conservative approach would place a 50 Ohm pad (6 to 10 dB) at the edge of the test fixture.

This photo shows the test fixture that we used with the EMRFD scheme. The inductor in this case is a ferrite toroid wound with Litz wire. This variable capacitor is believed to be made by Jackson Brothers, Ltd, from England and is the highest Q variable capacitor we had in our junk box. More on this below.

Comparing the methods.

Most of the measurements we have done in recent times used the EMRFD method. In years past, we
would use a Q meter when available, but most often, the 3 dB BW method. Short of a calibrated Q-Meter, the EMRFD scheme is quicker than the 3 dB resonator bandwidth measurement. In one recent case, I measured the Q of an inductor with both methods. The inductor was a basket weave coil, described below. Using the classic 3 dB bandwidth method, the Q was measured as 579 at 1 MHz. Insertion loss was 48 dB for this measurement. The same coil with the same variable capacitor measured Q=650 at 1 MHz with the EMRFD scheme. That’s about a 10% spread between the two schemes.

The coil used in this experiment was a 5 inch diameter solenoid wound in a basket weave pattern for L=265 uH. The wire was 175/46 Litz, which is 175 strands of #46. The coil sat on a piece of plastic suspended on a stack of wood blocks during measurement in an effort to avoid external loads.

Experiments with various coils.

APC cap with red/black leads (149 pF meter): 937Q at 904kc (Q meter alone and coil 1060Q)
APC cap with my Litz leads (149 pF meter): 995Q at 904kc (Q meter alone and coil 1060Q)

Steve's measurements above provide important datapoints with which to calibrate my technique. Note first of all that the Litz coil is not a modest 506Q but a robust 1140Q at 1MHz. The reason for my low measurement was my assumption of a high-Q capacitor. Steve's measurements of two of my APC's are 995 and 937, hardly very high. There is an obvious need for a correction. Wes Hayward in his excellent notes on Q measurements provides the key in the form of the following formula:

$$Ql = (Qc * Qres) / (Qc - Qres) \qquad (14)$$

where Ql is the desired coil Q, Qres is the measured Q of the tank/resonator, and Qc is the tank capacitor Q.

Substituting the values Qres = 532 and Qc = 995 the equation simplifies thus:
$Ql = (937 * 506) / (937 - 506)$
$Ql = 1100$.

The result is distressingly close to Steve's measured value of 1140Q. This shows the possible level of accuracy in the analytical technique used, both reassuringly high and very "Litz-like".

Taking the first solenoid and substituting the values Qres = 167 and Qc = 937 the equation simplifies thus:
$Ql = (937 * 167) / (937 - 167)$
$Ql = 203$.

my opinion that the capacitor Q ought to be high enough as to not influence the coil Q measurement in any significant manner. I said that for three reasons: 1) Just about every published article starts with such an assumption and 2) I had not done much research on the subject of capacitor Q and so had no particular expectations other than assumption 1 and finally 3) I had no measurements or specific knowledge of the Q for the capacitor used in my setup.

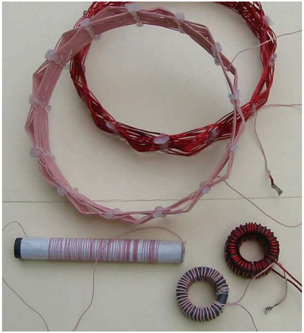
Reason 1 is a punt and should be rejected, reason 2 has been remedied and I give some analysis on the interesting subject of capacitor ESR (Equivelant Series Resistance) on a separate page so that readers may set their own expectations. For the third reason I have received the kind assistance of Steve Ratzlaff, AA7U who offered to make actual Q measurements on the coils and APC capacitors with his HP4342A Q-meter, results follow:

Litz basket coil,
550kc 1127Q;
1000kc 1140Q,
1700kc 674Q (194.2 uH on aade.com LC meter)

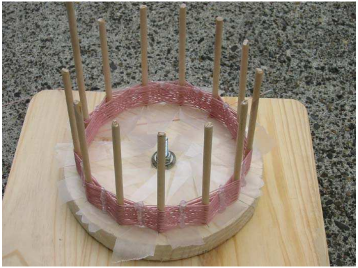
Solenoid coil,
550kc 205Q,
1000kc 240Q,
1700kc 222Q (218.2 uH on aade.com LC meter)

Using Steve's Litz wound ferrite rod coil (1000kc 1047Q) as the reference for external caps:

100 pF silver mica (99.2 pF meter):859Q at 1068kc (Q meter alone and coil 1025Q)



Some of the coils investigated in this study. The basket weave coils were wound with the fixture shown below. The two toroids shown are Amidon FT-114A-61 and used #18 enamel wire or 175/46 Litz wire. The rod is similar to an Amidon R61-050-400 and is wound with 50/46 Litz wire.



Fixture used to wind basket weave coils. Strips of waxed paper are placed under the coil cross over lines before application of hot melt glue.

Toroid Experiments

Most of the filters I build at HF use toroid cores. Powdered iron cores seem to offer higher Q at HF (3 to 30 MHz) than I can obtain with other practical, reasonable sized forms. The -61 and -63 Ferrite materials from Amidon offer high Q in the MF region from 300 kHz to 3 MHz. Powdered iron can provide high Q, but have such low permeability that the number of turns becomes excessive. So the first experiments I did used ferrite toroids.

Not all of the data collected will be presented here. However, I'll give a few of the data points of interest. There are some surprises.

qc = 18.55 exp(-t / 2*Rp*123)*cos(6.283*1.044*t + 1)

Where t = 0 to 50 uS
R = 0.627 Mohm in this case for best match.

Q = Rp / 2pifL = 627000 / 6.283 * 1.044 * 189 = 506

The results above for a big litz coil clearly demonstrate its superiority to a more common tapped solenoid. Published data though has let me to expect a big litz coil Q to be in the 1000+ range. I have run this test backwards and forwards, checking all possible causes for this unexpected low Q with no difference in the final value. In fact I am quite impressed with the repeatability of the technique and the correspondence between the results from the decrement and those from modeling the wave form.

To be certain I even tested the coil using the old -3dB method. As stated previously, I am uncomfortable using a signal generator in addition to the scope, and I have already found trouble connecting the 1:100 scope probe directly to the tank, as is necessary in this method. With that said, the results yield a bandwidth of 2.3kHz about a nominal frequency of 1018.8kHz for a tank Q = 450. I suspect the method (with the problems noted) lowballs somewhat the final result. In any case, this confirms the test to have a moderate Q and nothing like the expected values one reads online.

Notes on Capacitor Q and its impact on the measurement value.

This is where we begin to think more seriously about the capacitor used to resonate the tank. The assumption of very high Q needs to be questioned. I stated in the setup discussion

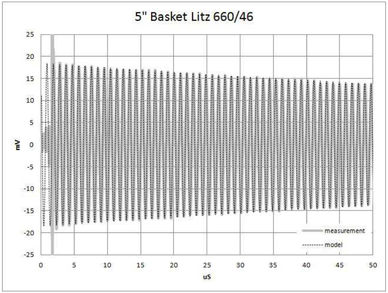


Figure 6. Second oscillogram with modeled damped wave response.

The coil tested values as follows:

$n = 45$
$T = (t_n - t_o) / n = (47.82 - 4.70)/45 = 0.958$ uS
$f = 1/T = 1/0.958 = 1.044$ MHz

$A_o =$ $= 18.05$ mV
$A_n =$ $= 13.65$

$d = 1/n \ln(A_o/A_n) = 1/45 \exp(18.05/13.65) = 0.00621$
$Q = \pi / d = 3.142 / 0.00621 = 506$

And:

$q_c = q_o * e^{(-t/2R_pC)} * \cos(2\pi f * t + \phi)$
$C = 123$ pF

First, the best toroid I found for BC band use was 38 turns of #18 enamel wire nearly filling a FT-114A-61 core. Inductance was 195 uH on an AADE L/C meter. Q=383 at 1 MHz and peaked up to almost 400 at 811 kHz. Q remained well over 300 at both 500 and 1610 kHz.

A slightly more practical and easier to wind coil used a FT-114A-61 form with 41 turns of #22 enamel wire. At 1 MHz, the inductance was 240 uH with a Q of 384. The Q dropped nearly to 300 at the band extremes.

The receiver I was building was to use a variable capacitor with only 188 pF maximum C. So a higher L was needed. I managed to get 56 turns of #22 enamel wire on a FT-114A-61 form for L(AADE) of 449 uH and Q=344 at 1 MHz. Q was 316 at 549 kHz and 274 at 1.55 MHz. Although compromised, this seemed a practical coil for a first zero power receiver.

A question that immediately came up was what could be done with Litz wire on toroids. The results were disappointing. 39 turns of 175/46 Litz wire on a FT-114A-61 form yielded L=244 uH and Q=318 at 1 MHz. The Q improved to 352 down at 550 kHz. A second FT-114A-61 core was wound with 40 turns of smaller 50/46 Litz wire, resulting in L=248 uH and Q=298 at 1 MHz. Again, low frequency Q improved slightly. My conclusion at this point is that the 175/46 Litz wire is not justified for ferrite toroids, although that conclusion is certainly more general than my data can support. I have not investigated any of the expensive Litz "rope" using over 600 strands of #46 wire. (See later note.)

Variable Capacitor Q (data updated 08Dec08 with more discussion at the end.)

Many of the web sites I read that deal with crystal sets and similar receivers state that the absolute best possible variable capacitors should be used. They then define these as being those capacitors with ceramic insulators, with silver plating being preferred on the metal. Double bearing designs are also recommended. Some sort of special means to minimize resistance related to moving contacts is deemed important. While all of these things are intuitively reasonable, they are not numbers.

The Q measurement schemes I have presented all relate to a determination of resonator Q. Actual inductor Q can only be obtained if one knows the Q of the capacitors in a tuned circuit, or if can be established that capacitor Q is very high. The folks building Q meters go to great extremes to optimize the variable capacitor Q within the instrument. (See Kito and Hasegawa, "Measuring Q" Easier and Faster,(HP Journal, September, 1970.)

Let me again emphasize that all of the numbers presented here, with all measurement methods, relate to resonator Q. We can calculate capacitor Q only if we independently know the inductor Q.

This still leaves us with the question of what we should be using for variable capacitors, both in our receivers and for Q measurement. To begin an evaluation, I took the highest Q toroid that I had built at the time (38 turns of #18 enameled wire on a FT-114A-61 core) and attached it to various variable and fixed capacitors from my junk box. Measurements were done at or near 1 MHz using the EMRFD measurement scheme. The data, although less than conclusive, is interesting. Here are some results:

decrement method. An exact match will not always be the case, but they ought to be fairly close. The match between theory and the decrement method gives confidence that this analytical technique is as robust as it is simple.

qc = qo * e^(-t/2RpC) * cos(2pif * t + phi)
qc = 12.2 exp(-t/2*Rp*106)*cos(6.283*1.055*t + 1)

Where t = 0 to 50 uS
R = 0.237 Mohm in this case for best match.

Q = Rp / 2pifL = 237000 / 6.283 * 1.055 * 215 = 167

Example Two:

To be sure the technique works I have also assessed the quality of a 5inch diameter basket weave coil wound from 660/46 litz wire. Such coils are rightly considered "performance coils" for their low skin-effect and low resistivity.

This leaves the resistance of the coil (R) as the primary variable. Model the above equation in the spreadsheet by adjusting R until the model results match the measured oscillation from the coil. From the above example we see Figure 5 with the modeled damped wave overlaid on the test oscillation.

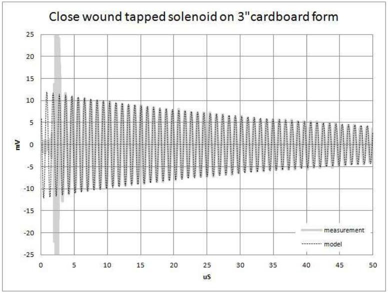

Figure 5. Oscillogram with modeled damped wave response.

Here the background data from the test is in grey and overlaying it is the dashed model in black. The fit is nearly perfect using a resistance of 0.22 Mohms. Relating resistivity to Q we have the following equation (5):

$Q = Rp / 2pifL$

Substituting f = 1.055 MHz, C = 106 pF, and R = 0.237 Mohms the result is Q = 167, exactly the same as with the

Capacitor comparisons, all operated near 100 pF.

1. 107 pF Silver Mica. This consisted of two series connected 214 pF 1% 500 volt units.
1. Resonator Q=341.
2. Mica compression trimmer, 30-300 pF, marked GMA40400, Resonator Q=314.
3. "Jackson Brothers" (that’s a guess) dual section, 497 pF/section max, built-in gear drive, Resonator Q=383. This was the best variable capacitor in my junk box.
4. TRW four section. This was the most elegant looking capacitor I had in my stash. It came from a Tektronix 191 sine wave generator. Resonator Q=354. An OK cap, but not the best.
5. Collins TCS Transmitter VFO capacitor, built-in gear drive. Resonator Q=357.
6. ARC-5 Receiver variable. (BC-454?, all three sections in parallel yield 47-514 pF) Resonator Q=378.
7. BC-221 capacitor, 13 to 188 pF, Resonator Q=364.
8. Hammarlund single bearing, 150 pF max. Resonator Q=279. (ugh).

Much of the lore seems correct. However, the best measured resonator Q came from the Jackson Brothers dual section, not from antiquity, but from just slightly more recent times. The beautiful TRW capacitor, while good, was not at the top of the list. The aging single bearing capacitor was not expected to be great, and there was no surprise. I was surprised that the Silver Mica fixed capacitors were not at the top. But perhaps these were rejects. Although they were brand new unused capacitors, they were purchased at a surplus emporium and loss may have been the reason they were declared surplus. Additional measurements are called for in this area.

Additional information regarding capacitor measurements is appended at the end of this note.

Litz Wire Connection.

Classic lore suggests that it is vital to solder all strands in a Litz wire bundle at both ends. If one strand is left unsoldered, the argument is that current can no longer flow in that wire, so it will not contribute to the expanded surface area that leads to improved Q with Litz wire.

I had measured less than stellar Q with some 175/46 Litz wire on a toroid form and wondered if perhaps I did not manage to get all of the strands soldered. So I did an experiment while using the mica compression trimmer as the capacitor (poor capacitor choice.) After doing my best to solder all strands by carefully applying rosin flux from a SMT rosin pen, I heated and tinned the ends with an 800 degree tip in my Weller soldering station. The ends looked very good in a visual inspection.

I then started doing Q measurements near 1 MHz. After each one, a few strands of the Litz wire were cut and a 1 inch section was removed near one end. The strands were removed from the capacitor end of the test resonator. Here’s a plot of Q from 0 to 152 clipped strands. N was estimated by counting the number of pieces of wire after a clipping operation.

To test the validity of this technique we need a bit more theory, just to be certain this is working. With the data in spreadsheet form, it becomes possible to model the coil from a theoretical standpoint. The model can then be plotted with and compared to the acquired data to test for correlation. Various web pages, especially university-sponsored lab exercises provide a good source for practical techniques and their theoretical underpinnings. Some good sources I utilized include:
"Damped oscillations in RLC circuits" by Barbara Dziurdzia at AGH University of Science and Technology in Cracow, "RLC Circuits" a lab note from Rice University, and "Oscillations and Resonances in LRC Circuits" from Durham University in the UK. And very many others.

From the above we find the general equation for damped electrical oscillations as:

qc = qo * e^(-a*t) * cos(2pif * t + phi) (13)

Where
qc is the charge in volts
qo is the initial charge
a is the damping factor (=Rs/2L (series) and = 1/2RpC (parallel)
R is the coil resistance in ohms
L is the coil inductance in uH
t is the time in uS
f is the frequency in MHz
and phi is the phase angle

The phase angle and qo charge are initial conditions and adjustments should be minor to fit the calculated oscillation to actual. L, the inductance comes from the calculation we made with equation (12), and frequency comes from equation (9).

An example to show off a bit. This test was made with a close-wound tapped solenoid on a 3" cardboard form. The graphic in Figure 4 shows some initial contact hash followed by a lovely damped oscillation. Measurements on this coil showed a test frequency of 1.055 MHz, L of 215 uH and C = 106 pF. Q was calculated at 167. A decent coil but not great.

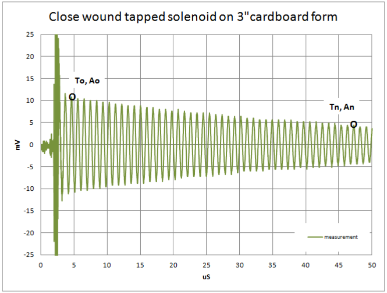

Figure 4. Oscillogram of a coil under test.

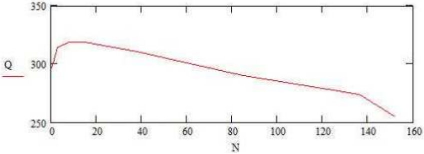
$n = 45$
$T = (t_n - t_o) / n = (47.24 - 4.59)/45 = 0.948$ uS
$f = 1/T = 1/0.948 = 1.055$ MHz

$A_o =$ $= 11.2$ mV
$A_n =$ $= 4.80$

$d = 1/n \ln(A_o/A_n) = 1/45\exp(11.2/4.80) = 0.01883$
$Q = \pi / d = 3.142 / 0.01883 = 167$



Q versus number of removed strands in a Litz wire toroid. There are 175 total strands in this wire.

This is certainly not a definitive experiment. It should be repeated with a coil where the Litz wire seemed to actually make a difference, and that was not the case with the toroid. However, the classic lore is not supported. But this makes sense after some thought (and some comments from colleague KK7B.) The weak dependence suggests that even though a cut at the end of a wire means that conduction is eliminated at the end of the wire, this does not mean that it is removed from the interior of the coil. Strand to strand capacitance guarantees that similar current will flow in each. The current in each forces the flow to the surface. If a strand is cut, there will still be some current flow in that strand back from the cut. The capacitance between strands connects the strands to those that are still connected at the end.

I hope to repeat this experiment with a different coil and a better resonator capacitor.

The Basket Case

Solenoid coils tend to have the highest Q if the wires are spaced by about 1 wire diameter. This lore is found in Doug DeMaw's book on Ferromagnetic Inductors (Prentice Hall,

1981) and is quoted on the Amidon web page. This rule of thumb is reasonable. The highest inductance will occur with tight spacing. If the spacing increases beyond this, there is a greater chance that some of the magnetic flux from one wire in a coil will escape from the side of a coil and not link to all turns.

If we plot the inductance of a solenoid of constant pitch versus the number of turns, L is proportional to N2 when N is small. However, the parabolic shape relaxes toward a linear dependence as N becomes large, especially as the length exceeds the diameter. Linear L versus N is akin to adding inductors in series where each one is isolated from the others.

When one turn is directly next to the next turn with no gap, the current flowing in one turn will force some of the current in the next wire to move away. The overall effect produces non-uniform current in the wire surfaces. This is alleviated with a slight spacing between turns. But too much spacing decreases inductance too much.

A classic coil type is the so called basket weave. A couple of coils of this type are shown, along with a coil winding fixture on page 7 of this report. There are an odd number of rods in the winding jig. This means that as we weave the wires among the rods, one turn will not be directly adjacent to the next turn. This makes the coil behave as if it was a solenoid spaced by 1 turn. But there is no real gap, so the coil length, and hence, inductance is the same as a tightly wound one would be.

I had never built a basket weave coil, yet this is one of many designs that the folks describe on the web sites mentioned. So a couple of coils were built. The first used #22 enamel wire. The coil diameter is 5 inches wound on 13 posts with a total of

5000 data points to the computer. At 1 MHz that is about 100 data points per cycle, more than enough sampling to avoid any question of aliasing.

The decrement measurement is based on measuring two peaks. The data is in digital format so one should eliminate "estimation error" by actually reading the value off the spreadsheet, noting both time (in uS) and amplitude. Before taking readings, care must be taken to center the oscillations around zero. Amplitude measurements assume that the waveform is symmetrical around zero yet the scope may or, more likely, may not be set perfectly for this. In the spreadsheet the solution is simply to take the average of all the readings and subtract that from each.

Type the values for “to” (initial peak time), “tn” (final peak time), Ao (initial peak amplitude) and An (final peak amplifude), and the number of periods analyzed “n”.

T = tn - to in uS (8)
f = 1/T in MHz (9)

d = 1/n ln(Ao/An) (10)
Q = pi / d (7)

Next, disconnect the battery and coil and measure carefully the capacitance, C, that was used in the test. With this you can calculate the actual coil inductance from the frequency and capacitance. Why buy an expensive L meter?

L (uH) = 1E6 * ((1/ 2pif)^2) / C (pF) (12)

Example One:

10uS / division for a longer recording. Set the scope trigger appropriately to capture the data.

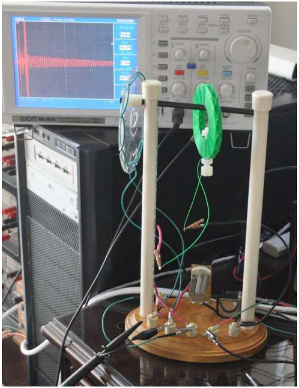


Figure 3. Photo of the test setup.

Tap, or "key" the battery to pulse the tank and review the waveform on the screen. Setting the scope on its measurement mode allows reading the wave frequency with each pulse. Adjust the capacitance after each pulse to bring the tank to the desired frequency, near 1 MHz in my case. Once at the desired frequency you are collecting data. When you get a good clean oscillation free of contact hash and noise, send the data to the computer for analysis. For my scope set at 5uS/div it returns

---

36 turns. The 1 MHz Q was a poor 244 with Q slowly increasing with frequency. Inductance was 265 uH A similar coil was then wound with 175/46 Litz wire. Again, inductance was 265 uH. The 1 MHz Q was a spectacular 650. The Q dropped off at both 530 and 1630 kHz, but was OK over most of the range. This is the highest 1 MHz Q I had ever seen at that time. I remember frequent Q values well over 1000 with some helical resonators at 500 MHz, but that is common at UHF.

Ferrite Rod Experiments

The next resonator type to be investigated was the ferrite rod. The only new part that I had around was an Amidon R33-050-750, meaning that it was built from mix 33 type ferrite with a diameter of 0.5 inch and length 7.5 inch. This material has an initial permeability of 800, which is high enough to make me wonder about it as a high Q antenna material. Owing to the high permeability, the number of turns needed should be much less than the 70 turns suggested in the N7FKI paper. I put a layer of paper on the core and then would 36 turns of #22 enamel wire over the central 3 inches. The inductance was 158 uH. Additional turns would be needed to reach the desired 240 uH.

Then Q was measured. It was a miserable 58.6 at 1 MHz. On the other hand, I did see several local radio stations in the spectrum analyzer display during testing. It may be a viable antenna, but it is not much as a resonator. I didn’t even bother changing to Litz wire.

The next experiment was with a junk box ferrite rod. This was a piece that was 3.85 inches long with a diameter of 0.475 inch. After putting a layer of paper on the core, I wound 37 turns of #22 enamel over the inner 2.8 inches. The inductance was 80 uH. A 1 MHz Q measurement was a more respectable 293.

The dimensions of this rod were very close to an Amidon R61-050-400. The inductance constant in the Amidon literature, after conversion, was 43 nH/turn2, so the 37 turn winding should have an inductance of 59 uH if it was wound evenly over the total core. My winding was bunched near the center which would increase the inductance a bit, so 80 uH would be reasonable. I concluded that the material is probably -61 mix, or a similar mix with initial permeability of 125, perhaps from a different vendor. I calculated that 65 turns over the same part of the core would yield 250 uH.

Based upon the measurements above, I wound 62 turns of 50/46 Litz wire on a single layer of paper over the junk box rod. The result was a spectacular Q of 610 at 1 MHz. The Q dropped off to 577 at 550 kHz and 500 at 1551 kHz, both still quite respectable. This high Q was a major surprise.

N7FKI has a larger R61-050-750 ferrite rod in his parts box and has offered it for some measurements. That is on the list of "To Do" experiments.

Classic Solenoid Coil

Among the goodies in the N7FKI junk box were some large cylinders that looked like they would work well as coil forms and yield reasonable Q. The outside diameter was 4.2 inches. After earlier coil construction experiments, about 55 feet of Litz wire remained on a spool (purchased on EBay from Paul Cianciolo, W1VLF), so I put solder lugs on each end and wound a coil. The first one had the wires spaced approximately

pF. These are silver or nickel plated (depending on the source of information) and ceramic (steatite) insulated and should have a high Q with little impact on the test. At least this is the general assumption used in most Q-measurement articles I have run across. In actual fact the capacitor Q is not infinite and not even that high so resistive losses associated with the capacitor can be expected to lower the measured Q. One needs to keep this in mind and know that this measurement is on the resonator, not on the coil itself. More on this topic in a later section. The APC capacitance range is limited but sufficient for my intended test frequencies of 1.0 to 1.1 MHz, this is a test, not a radio.

Keying, or pulsing the circuit is somewhat tricky. In order to obtain a clean wave trace the pulse contact needs to be fast and sharp. Contact "bounce" and arcing, especially at radio frequency are difficult to avoid and pulsing the circuit several times may be needed prior to finding a clean trace. I initially used a transmitter key but found the contactor at RF to be messy with visible arcing. The best method I have found for pulsing the circuit is to connect a pointed probe to one side of the circuit and tap it sharply but lightly against the hot side of the battery. After a few tries one gets a "feel" for the contact. Pulse the circuit and get a wave, things are this simple.

Procedure:

Hang the coil under test on a stand where it is clear of other components or metal objects. Connect the coil as per the schematic. Connect the probe and scope to the coupling coil leads and set the scope for a good scale, (Figure 3). I generally use 5uS / division horizontal scale which gives me 40 to 50 oscillations at about 1 MHz. For higher Q coils I may go to

Setup:

The following schematic shows the setup, (Figure 2). In this configuration, I have used a simple 9V battery to stimulate the coil and have the scope connected to the tank via a coupling coil. An earlier configuration with a power supply resulted in too much noise and ripple to obtain a good reading. The tank is coupled lightly to the scope with a coupling coil. This coupling coil is simply two turns of hookup wire about 4 inches in diameter placed an inch or two from the coil to be tested and I have found no reason to space it further. Between the coupling coil and oscilloscope I utilize the 1:100 probe although testing with my 1:10 probe showed little impact. In this way, the coil under test is clean and well isolated from the measurement circuit.

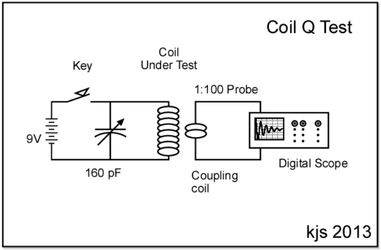

Figure 2. Schematic of test circuit.

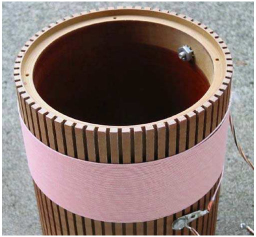
For the tank I have used a small CT1C150 military spec cap ("APC"-type) with a capacitance range from about 20 to 160

with a 1 wire diameter gap. Measured inductance with the AADE L/C meter was 275 uH. The Q at 1 MHz was 353; OK but disappointing. The winding length was 2.9 inches.

The coil was then rewound with close spacing, resulting in 53.25 turns over a length of 1.52 inches. Inductance with the AADE meter was 378 uH. A 1 MHz Q measurement showed a higher effective L of 419, but with Q=219.



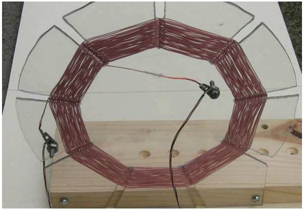
Close spaced solenoid coil.

I have not discussed the self resonant frequency of any of the inductors described in this note. However, it is easily measured by merely inserting the inductor in a 50 Ohm line. The fixture on page 6 of this note can be used. The "through" wire between the BNC connectors is removed and the coil is inserted. The signal generator is then tuned to find the first null frequency. This null is the result of stray parallel C resonating with the inductance to form a trap. The parallel resonant frequency was 4.0 MHz for the close spaced inductor shown in the above photo. This inductor had an inductance of 378 uH, which was measured at about 500 kHz with the AADE L/C meter. This yields an equivalent parallel capacitance of 4.2 pF. Using this and the 378 uH inductance measurement we calculate an effective 1 MHz L of 403 uH. This is still below the value we measured. The AADE number may well be in error because of the coil's parallel capacitance. Additional number crunching should yield a better model.

Update: 01Dec07

A Spider Coil.

Many of the crystal radio related web sites present information on Spider coils. I picked up a piece of Lexan Polycarbonate at Home Depot and cut it to form a nine segment coil form. The diameter ranged from 4.4 to 6.1 inches. This form was then wound with 39 turns of the 175/46 Litz wire. A photo follows.



The inductance was 373 uH, but the Q results were disappointing at best: 550 kHz, Q=499; 1.002 MHz; Q=474; 1.504 MHz, Q=382. The EMRFD Q measuring scheme was used.

be related to the circuit components as follows, (Bucher, 1919):

d = pi (R / 2pifL) (3)

The angular frequency is often expressed as w= 2pif so this can be substituted into equation (3) above to simplify as

d = pi R / w L (4)

We turn now to looking at Q and its relation to the circuit components. The general expression for Q is:

Q = 2pifL / R (5)

Simplifying to

Q = w L / R (6)

With the term w L in both expressions, we can solve for w L in each and set them equal to each other:

QR = piR / d so:

Q = pi / d (7)

Dreadful, wasn't it? The inspiration here is that with a simple determination of the logarithmic decrement, deriving the circuit Q is a trivial exercise even a geologist can manage. No signal generators, no attenuators, no multiple measurements. All this should serve to reduce sources of error and give a faster and easier way to determine the quality of that most central component of your crystal radio, the coil.

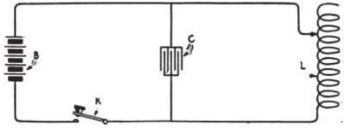


FIG. 8. Simple oscillation circuit illustrating the production of radio frequency currents.

Figure 1. Simple oscillation circuit, Bucher 1919.

As a professional Geologist, I must admit that most math involving more than ten fingers and ten toes (for advanced computations) is not my specialty. As such I will keep this aspect to an absolute minimum. Still, a bit of algebra may be useful to explain damping and logarithmic decrement. RF oscillations in a tank circuit are damped due to losses (primarily resistive) associated with that circuit. The amount of damping thus is related to the quality, or Q of the tank. In old texts the damping is generally determined by measuring the "Logarithmic Decrement" or the amplitude of successive oscillation peaks and taking the log of the ratio.

$$d = \ln(A1/A2) \tag{1}$$

A more generalized version of this formula taking into account measurements over many periods can be expressed as:

$$d = 1/n \ln(Ao/An) \tag{2}$$

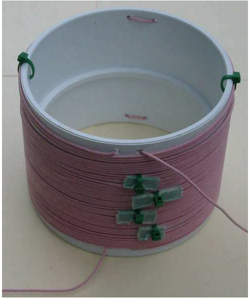
Where n is the number of periods analyzed, Ao is the amplitude of the first peak and An is the amplitude of the peak n periods away. This equation allows a very simple determination of the log decrement with high accuracy. Because damping is due to resistive losses in the circuit, it can

Using Litz Rope.

The initial experiments were encouraging, although I was frustrated in not having achieved higher Q values. A review of many sites on the web quoted "Q over 1000" as if it was to be expected. One of the most informative web sites that I found was from Europe, http://www.crystal-radio.eu/enlctest.htm . He built numerous coils and then did careful Q measurements. Many of his measurements were consistent with mine. There was one central theme that emerged: If Q in excess of 1000 is desired, it is probably achievable only with Litz wire using many more strands than the 175 that I had used. Specifically, the wire that really made the difference in the measurements from Europe was 660/46 Litz. This is 660 strands of #46 wire. I’ve seen this stuff referred to as "Litz Rope," although that term is often reserved for the bundles that are up to two inches in diameter. The 660/46 wire is manufactured by Kerrigan-Lewis. They will sell to individuals, but have a 2 pound minimum. That’s a lot of rope. You can find smaller pieces of this wire for sale on the web, but with a high price tag.

Then my experiments expanded to the next level. This was the result of an unexpected package that showed up in my mail box. I opened this offering to discover a 54 foot piece of the 660/46 Litz rope, plus a most interesting letter. My benefactor was Steve, AA7U. Steve’s letter also mentioned the coil form that many of the crystal set guys use, a 4.5 inch OD coupler for large PVC pipe. I quickly purchased some. The part was found in the bins at Home Depot where it is their part number 405* and is marked "4 IN COUPLING HUBXHUB" and "(STYRENE)". The form cost was just over $1. Steve had done careful measurements of coils using this form and 660/46 Litz Rope.

I quickly wound the coil shown below.



The photo does not really tell us about coil length. This coil has the 44 turns spaced to occupy 3 inches of the 3.6 inch form length. The wire is held in place at the ends with holes in the form. Small cable ties are then used to keep the windings from moving. I wanted to preserve the integrity of the Rope for additional experiments, so did not want to apply any glue. I cut some small strips of Plexiglas with filed notches. These strips are then placed over a pair of holes drilled in the form so that three wire turns are covered. The cable tie is then inserted.

The results were outstanding; finally, Q>1000. The details with the EMRFD Q measuring scheme:
F=550 kHz Q=1199
1011 kHz Q=1375
1600 kHz Q= 973 Steve's results with a similar coil were 1276, 1426, and 1129 at approximately the same frequencies.

frequency. The tank is generally energized with a signal generator and measured with an oscilloscope or sensitive digital voltmeter. Other components often may include attenuators, SWR analyzers, Spectrum analyzers etc. Sources of error enter with coupling, loading, uncertainty as to the actual internal resistance of the source generator, and the need for several independent measurements which are then multiplied or divided together, adding additional error. All this works very well for the engineer with good bench practice, good equipment ($$), and the patience to perform the measurements several times to check repeatability. All these things plus the required anality coefficient the current author lacks.

In this paper I propose an alternative approach that takes an analytical look at the oscillating tank waveform and determines the coil Q from that. This technique dispenses with a majority of the equipment involved with traditional methods but does require a digital oscilloscope. In recent years the affordability of these scopes has greatly increased. If you have a digital scope, or access to one, or were looking for an excuse to purchase one, then read on, this technique may be for you.

Some Theory:

The inspiration for this technique is certainly not new. I first found the following simple circuit, (Figure 1) on page 22 of Bucher's 1919 "Wireless Experimenter's Manual". Having a good deal of experience capturing and evaluating damped radio oscillations for a Spark Gap transmitter, I immediately saw the utility of the circuit for a simple Q determination based on the damping decrement of the tank.

An Analytical Approach to the measurement of coil Q

http://www.lessmiths.com/~kjsmith/crystal/coilqm.shtml

Kevin Smith

Background:

Measuring the values of your radio components is an interesting and fun part of the Crystal Radio Hobby. Not only does it help you design better radios, but helps to understand the physics behind the wires and plates. The radio coil, one of the principal components is generally that part wound by hand. All other components, diode, variable capacitor are usually bought ready-made. The coil sits at the heart of the set and yet it remains devilishly difficult to measure and characterize. Even cheapo inductance meters, (I mean, my cheapo meter) do not properly measure the coil inductance at radio frequency. Coil quality, well that is a whole other matter. Quality, or the Q-factor as it is often called is a bench-intensive and measurement-intensive proposition that even the most dedicated radio fan may shy away from.

If you wish to know your coil Q-factor you have the choice of tracking down and paying a lot of money for an old HP or Boonton Q-Meter, or setting up a test bench and making the required measurements yourself. A number of techniques for measuring the Q of a coil have been published and excellent summaries can be found in "Q Factor Measurements on L-C Circuits" by Jacques Audet, and "Experiments with Coils and Q-Measurement" a web page by Wes Hayward.

All the techniques discussed involve variously setting up a parallel or series tank containing the coil to be tested and an accompanying capacitor to tune it to the needed measurement

---

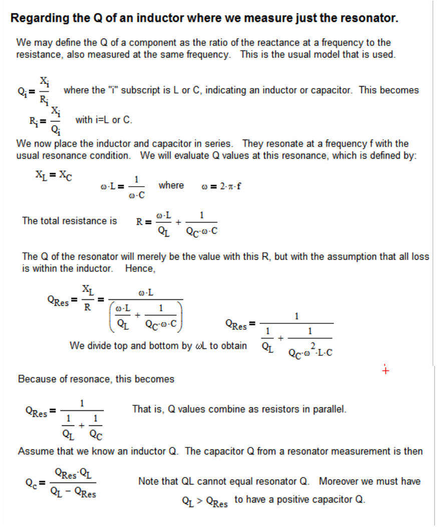
Steve used a traditional 3 dB bandwidth measurement to establish Q, but with the coil tuned by the variable capacitor in a HP4342A Q meter. That Q meter stops at values of 1000.

Although I was pleased to have finally reached a Q goal, the measurement correlation was of equal significance to me. This data is further validation of the EMRFD Q measurement scheme. The Q values that are slightly lower than those that Steve obtained can be attributed to losses in the variable capacitor I used and to experimental error. These values are consistent with those reported in the crystalradio. eu web site listed above.

Recent examination of capacitor Q. (December 8, 2008.)

The earlier information regarding variable capacitor Q was confusing. That info, starting on page 8, has been modified to emphasize that my measurements are of total resonator Q. Although I have yet to do additional measurements, I did a few calculations that are illuminating.

We begin with analysis to derive a suitable formula. This is shown below in a MathCad work sheet.



Regarding the Q of an inductor where we measure just the resonator.

We may define the Q of a component as the ratio of the reactance at a frequency to the resistance, also measured at the same frequency. This is the usual model that is used.

$Q_i = \frac{X_i}{R_i}$ where the "i" subscript is L or C, indicating an inductor or capacitor. This becomes

$R_i = \frac{X_i}{Q_i}$ with i=L or C.

We now place the inductor and capacitor in series. They resonate at a frequency f with the usual resonance condition. We will evaluate Q values at this resonance, which is defined by:

$X_L = X_C$

$\omega \cdot L = \frac{1}{\omega \cdot C}$ where $\omega = 2 \cdot \pi \cdot f$

The total resistance is $R = \frac{\omega \cdot L}{Q_L} + \frac{1}{Q_C \cdot \omega \cdot C}$

The Q of the resonator will merely be the value with this R, but with the assumption that all loss is within the inductor. Hence,

$$Q_{Res} = \frac{X_L}{R} = \frac{\omega \cdot L}{\left(\frac{\omega \cdot L}{Q_L} + \frac{1}{Q_C \cdot \omega \cdot C}\right)}$$

We divide top and bottom by ωL to obtain $Q_{Res} = \frac{1}{\frac{1}{Q_L} + \frac{1}{Q_C \cdot \omega^2 \cdot L \cdot C}}$

Because of resonace, this becomes

$Q_{Res} = \frac{1}{\frac{1}{Q_L} + \frac{1}{Q_C}}$ That is, Q values combine as resistors in parallel.

Assume that we know an inductor Q. The capacitor Q from a resonator measurement is then

$Q_c = \frac{Q_{Res} \cdot Q_L}{Q_L - Q_{Res}}$ Note that QL cannot equal resonator Q. Moreover we must have $Q_L > Q_{Res}$ to have a positive capacitor Q.

MathCad work sheet showing analysis.

Armed with the final formula in the above sheet, we can examine the capacitor Q data in more detail. We did this with Excel, beginning with a summary of the data and a "plot"

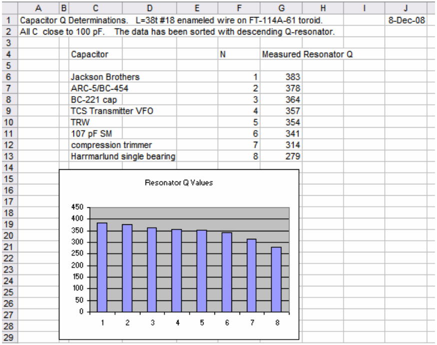
showing the results. The plot is just a bar chart and serves only to illustrate that most of the results are close to each other. Only one resonator Q was below 300, the result of a single bearing variable capacitor. None of the resonator Q values exceeded 400. This is shown below.



Capacitor Q Determinations. L=38t #18 enameled wire on FT-114A-61 toroid. 8-Dec-08

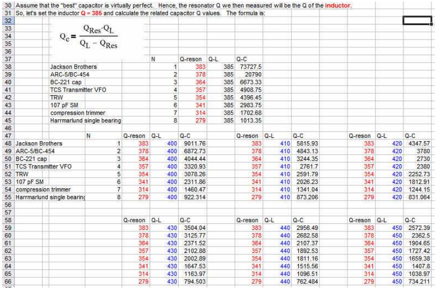
Sorted and plotted Capacitor impact on Resonator Q.

Having generated the bar chart, we proceeded to use the spread sheet to do some “what if” investigations. The first analysis assumed that out best capacitor was very good, so the highest resonator Q that we measured was almost the inductor Q value. If that really was the case, we can then calculate capacitor Q values. This case is at the top of the following page with QL=385.. After that, we assumed even higher inductor Q values and calculated the resulting capacitor Q results. See the next page.



Assume that the "best" capacitor is virtually perfect. Hence, the resonator Q we then measured will be the Q of the inductor.
So, let's set the inductor Q = 385 and calculate the related capacitor Q values. The formula is:

$$Q_c = \frac{Q_{Res} \cdot Q_L}{Q_L - Q_{Res}}$$

Spreadsheet showing a variety of capacitor Q values resulting from assumed inductor Q (in blue) and the measured resonator Q values (in red.)

The results are interesting. If the best measured Q is indeed mostly that of the inductor, we see that most of the capacitor Q values are high with even the worst still over 1000. If we slowly allow the inductor Q to increase in our "thought experiment," the capacitor Q values begin to drop. However, the best of the lot are still several thousand. While none of this conjecture is really hard data, it certainly makes us feel more comfortable with inductor Q values close to 400 and that it is valid to assume high capacitor Q.

Examination of the central equation is revealing. It is clear that if the inductor Q becomes much higher, we will be able to

obtain much better data about the capacitors. The most recent inductor built has a Q that is three times higher than the one used for the capacitor difference. The next experiment is obvious and will be in the next update to this note.

Acknowledgements

Thanks go to my son Roger, KA7EXM, to colleagues Rick, KK7B, and Bob, N7FKI, for numerous discussions. Bob also provided some critical parts for my experiments. Special thanks go to Steve Ratzlaff, AA7U, for the crucial Litz wire that so greatly enhanced the experiments.

Do = Diameter of the finished cable over the strands in inches = 0.056
K = Constant depending on the number of strands = 2

Rac/Rdc = 1.0003 +2(660*0.0016 / 0.056)^2 * (0.0016*1000 / 10.44)^4 = 1.393

Therefore the AC Resistance of 660/46 litz wire is approximately:

The A.C. resistance is: 1.39 * 7.27 = 10.13 ohms/1000ft.

A 5inch diameter basket weave coil made from 660/46 Litz wire having an inductance of 230 uH will typically require some 40 turns or about 53ft of wire. At 10.13 Ohm/kft, that comes to an AC wire resistance of 0.53 ohms for the coil alone. Were all the losses represented by series resistance of the wire, the coil would have, at 1 MHz an unloaded Q = 2700! Naturally, wire resistance is not the only source of loss in the tank. There is a capacitor, metallic objects intruding into the magnetic field of the coil, diaelectric losses, eddy current and other losses. Its no wonder that the best coils just top out above Q = 1000 or so.

This is where I leave things. Time to get measuring. Below I provide my input data, have at it!

Kevin Smith

*Note that in 1925 the importance of coil Rs was understood, but the factor Q was apparently not used. I have taken (quite painfully) the L and Rs data from their plots and calculated the resulting Q. I recommend to those interested to download the pdf of their paper.

The following calculation is made to determine the AC resistance of the Litz wire used in a coil:
From different Litz wire manufacturing sites one can find tables and data allowing the calculation of the resistance of your favorite litz wire.

The formula for the D.C. resistance of any Litz construction is:

Rdc = Rs (1.0515)^Nb * (1.025)^Nc / Ns

Where:
Rdc = Resistance in Ohms/1000 ft.
Rs = Maximum D.C. resistance of the individual strands (4544 for 46awg wire)
Nb = Number of Bunching operations (assume = 2)
Nc = Number of Cabling operations (assume = 1)
Ns = Number of individual strands (assume = 660)

Rdc = 4544 (1.015)^2 (1.025)^1 / 660 = 7.27 ohms / 1000 ft.

The ratio of AC resistance to DC resistance of any Litz construction is:

Rac/Rdc = S + K (N Di / Do)^2 * G

Where:
S = Resistance ratio of individual strands when isolated (1.0003 for 46awg wire)
G = Eddy Current basis factor = (Di * sqrt(f) / 10.44)^4
F = Operating Frequency in HZ (assume 1MHz)
N = Number of strands in the cable = 660
Di = Diameter of the individual strands over the copper in inches = 0.0016

RADIO-FREQUENCY RESISTANCE AND INDUCTANCE OF COILS USED IN BROADCAST RECEPTION

By August Hund and H. B. De Groot

ABSTRACT

This paper gives experimental data on the radio-frequency resistance and inductance of certain "low loss" coils within the range of broadcast frequencies. The coils are of different shapes and wound with different kinds of wire. The results are plotted in graphs so that the reader can use them for selecting a coil for a desired purpose. For the data to apply it is necessary that the coil be constructed in accordance with the information given in a table. The dimensions are such that the coils are suitable for modern broadcast reception. A discussion of the important characteristics of coils is given. Of the coils measured the loose basket weave coil and the single-layer coil have the lowest radio-frequency resistance. Where a binder is required for holding the turns in position, collodion introduces the least amount of resistance. For the entire range of broadcast frequencies (500 to 1,500 kc) No. 32-38 litz has somewhat smaller resistance than No. 24 AWG d. c. c. wire; however, for most work No. 24 wire is suitable.

I. INTRODUCTION

The purpose of this paper is to present data on the radio-frequency resistance and inductance of coils within the range of frequencies used in radiotelephone broadcasting. The coils are of different shapes and wound with different kinds of wire. The method of measurement used is indicated in Figure 1; it was described in detail by one of the authors[1] in 1924. The effective resistance R was found by direct comparison with a standard variable resistance R_s

---

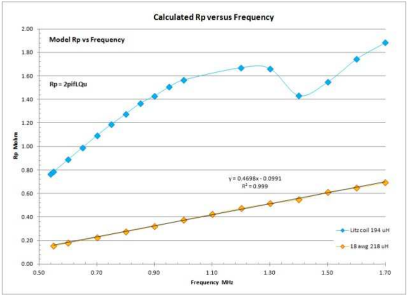
651

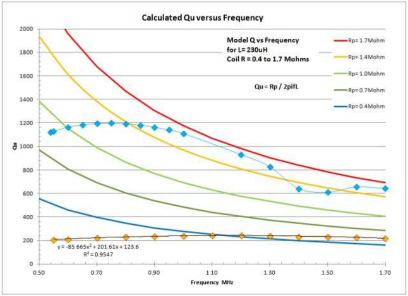
also includes Q vs f curves at constant Rp values. It is clear that, while tuning across the BCB spectrum, the Rp of the coil changes continuously.



Calculating the coil Rp from the data (Q:C:f), I have reproduced the above graph of the coil Rp vs frequency. It is evident that the trend follows a perfectly straight line for the low-Q coil. I would expect a similar straight-line relation for the litz coil but again things look strange. My impression here is that of a much steeper Rp vs f relation where the calibration on the Q-meter breaks down near 1MHz (Rp ~1.5 MOhm) and the data wanders until a second linear trend (with about the same slope) is re-established between 1.4 to 1.7MHz.

Now time for a few calculations, just how good can a coil Q get?

tuned a big litz coil with cheapo capacitors. Having an idea of your set's Ql will allow a better selection of the proper diode for matching.



The above plot is from a series of measurements on two of my coils kindly made for me by Steve Ratzlaff, AA7U. The blue diamonds are the measurements on a 660/46 Litz basket beast and the yellow diamonds are measurements on a modest 18awg tapped solenoid wound of a cardboard form. The data from the low Q coil form a lovely continuum across the BCB band while the litz coil data above 1MHz or so seem to be declining and erratic. Steve measured the coil a great many times and found good consistant results. The measurements are excellent but I must say, I am a bit suspicious that the high-Q coil may be at the limit of the HP Q-meter calibration, or perhaps 660/46 litz Q tops out at 0.7-0.8 MHz and crashes above that. (I have not yet found time to persue this). The plot

after the test coil and the condenser C had been tuned to resonance. The apparent inductance was calculated from the formula

$$L = \frac{25350}{f^2 C}$$

where the inductance L is in microhenries, frequency f in kilocycles per second, and the measured resonance capacity C of the series condenser is in microfarads.

II. PROCEDURE

The method employed was to compare at radio-frequency coils of several types commonly used in receiving sets. The coils had been adjusted to the same self-inductance at a frequency of 1 kc per second. This represents the minimum value of the apparent inductance, larger values being obtained at the broadcast frequencies. The direct-current resistance was different for the various coils, since some shapes required more wire than others for the same inductance at 1 kc.

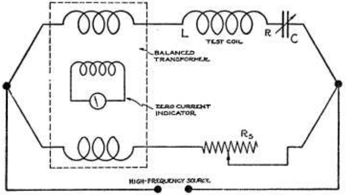


FIG. 1.—*Arrangement for the determination of radio-frequency resistance and inductance*

The quality of coils can be considered in terms of a number of different properties,[2] each of which is of importance in the use of

---

[2] It may help the reader to recall that the function of the coil is essentially to introduce inductance in the circuit, a given amount of inductance being introduced with the minimum possible length of wire and of resistance. On account of the capacity action of a coil the apparent inductance is usually much larger at broadcast frequencies, since the decrease due to skin effect action is small in comparison. The capacity action of a coil tends to transfer more or less energy across the turns than along them, thus turning the coil with increasing frequency gradually into a condenser with a resistance which is due to the insulation between the turns.

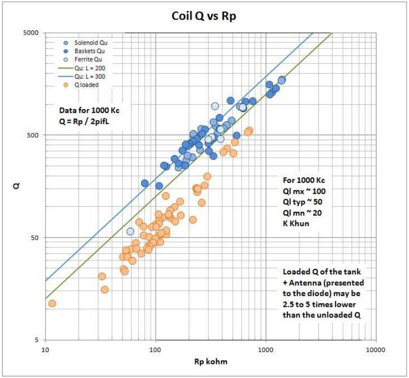
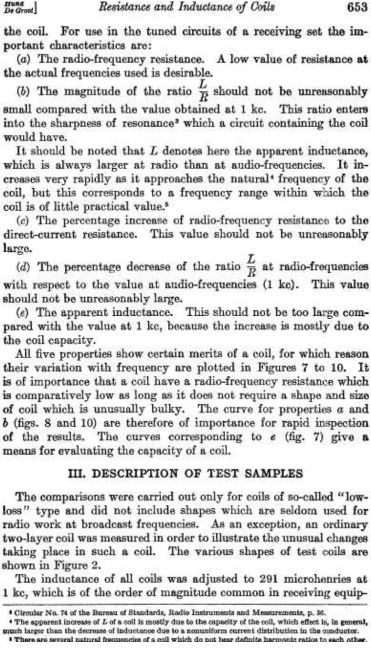
FIG. 2.—*Low-loss coils used for measurement*



On the plot I also post in orange circles my estimate of what the loaded Q presented to the diode (Antenna + Tank) might look like. Loaded Q will always be lower than the unloaded Q by several times. I have estimated that high-end sets (big litz, silver-plated ceramic insulated caps, best wiring practices) may lower the Q by about 2 1/2 times (B Tongue's performance set has Q = 700). At the low end (vintage components, small solid wire coils, taps) the load may lower Q by up to 5 times. Ken Khun in his excellent web book states that typical sets at 1Mhz have a loaded Q between 20 and 100, 50 typical and this is where most of the data falls. I scaled the divisor by Qu to produce the above plot but note that this is merely an estimate. Somewhere some bloke has no doubt cardboard form, sealed, of course. With various "open" coils, spiderweb, basket weave, diamond weave, etc. you may expect to double that.. possibly. The advantage in open coils derives from first the separation between adjacent wire turns which reduces self-capacitance in the coil, and secondly from the obvious lack of a form. All materials used in the coil will have some amount of dielectric losses associated with them and the less material used the better. Air core coils are best in this respect. I am not here to speak about ferrite coils as I have no experience with them. Frankly, they seem (to me) a bit like cheating.

The following graph presents data that I have scoured off the web. My primary sources include Hund and Groot, 1925*, Wes Hayward, Dave Schmarder, Ken Khun, Mike Tuggle, Steve Ratzlaff, and Dick Kleijer. 10,000 thanks for those who post their data on the web! The following plot gives the Q value as a function of coil Rs (series resistance. In striving for a high Q coil, in effect one is eliminating losses and lowering the series resistance as much as possible. There is more to it of course. The Q formula Qu = 2pifL / Rs tells us that Q is also a function of the coil inductance L and the frequency f of the measurement. All measurements chosen for plotting are made around 1 Mhz and most of the coils are in the L = 200 - 350 uH range. So, despite the formula, in this plot the coil Rp is the main driver. From the plot it should be apparent that winding a coil with Q = 200 or better should be a no-brainer. If your coil Q is less, you just aren't trying. At the high end, Q's > 1000 seem to be pretty extreme and these coils are expensive. You better be using big Litz 660/46 and use a basket design (although the two best coils on the plot were solenoids).



the coil. For use in the tuned circuits of a receiving set the important characteristics are:

(*a*) The radio-frequency resistance. A low value of resistance at the actual frequencies used is desirable.

(*b*) The magnitude of the ratio $\frac{L}{R}$ should not be unreasonably small compared with the value obtained at 1 kc. This ratio enters into the sharpness of resonance[3] which a circuit containing the coil would have.

It should be noted that L denotes here the apparent inductance, which is always larger at radio than at audio-frequencies. It increases very rapidly as it approaches the natural[4] frequency of the coil, but this corresponds to a frequency range within which the coil is of little practical value.[5]

(*c*) The percentage increase of radio-frequency resistance to the direct-current resistance. This value should not be unreasonably large.

(*d*) The percentage decrease of the ratio $\frac{L}{R}$ at radio-frequencies with respect to the value at audio-frequencies (1 kc). This value should not be unreasonably large.

(*e*) The apparent inductance. This should not be too large compared with the value at 1 kc, because the increase is mostly due to the coil capacity.

All five properties show certain merits of a coil, for which reason their variation with frequency are plotted in Figures 7 to 10. It is of importance that a coil have a radio-frequency resistance which is comparatively low as long as it does not require a shape and size of coil which is unusually bulky. The curve for properties *a* and *b* (figs. 8 and 10) are therefore of importance for rapid inspection of the results. The curves corresponding to *e* (fig. 7) give a means for evaluating the capacity of a coil.

III. DESCRIPTION OF TEST SAMPLES

The comparisons were carried out only for coils of so-called "low-loss" type and did not include shapes which are seldom used for radio work at broadcast frequencies. As an exception, an ordinary two-layer coil was measured in order to illustrate the unusual changes taking place in such a coil. The various shapes of test coils are shown in Figure 2.

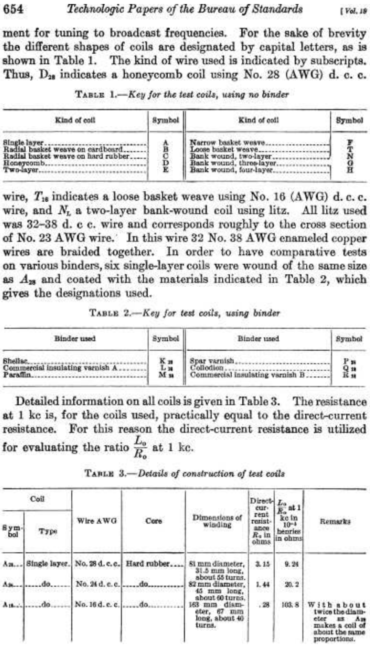
The inductance of all coils was adjusted to 291 microhenries at 1 kc, which is of the order of magnitude common in receiving equip-

---

[3] Circular No. 74 of the Bureau of Standards, Radio Instruments and Measurements, p. 36.

[4] The apparent increase of L of a coil is mostly due to the capacity of the coil, which effect is, in general, much larger than the decrease of inductance due to a nonuniform current distribution in the conductor.

[5] There are several natural frequencies of a coil which do not bear definite harmonic ratios to each other.



654 *Technologic Papers of the Bureau of Standards* [Vol. 19

ment for tuning to broadcast frequencies. For the sake of brevity the different shapes of coils are designated by capital letters, as is shown in Table 1. The kind of wire used is indicated by subscripts. Thus, D_{28} indicates a honeycomb coil using No. 28 (AWG) d. c. c. wire, T_{16} indicates a loose basket weave using No. 16 (AWG) d. c. c. wire, and N_L a two-layer bank-wound coil using litz. All litz used was 32–38 d. c c. wire and corresponds roughly to the cross section of No. 23 AWG wire. In this wire 32 No. 38 AWG enameled copper wires are braided together. In order to have comparative tests on various binders, six single-layer coils were wound of the same size as A_{28} and coated with the materials indicated in Table 2, which gives the designations used.

TABLE 1.—*Key for the test coils, using no binder*

Kind of coil	Symbol	Kind of coil	Symbol
Single layer	A	Narrow basket weave	F
Radial basket weave on cardboard	B	Loose basket weave	T
Radial basket weave on hard rubber	C	Bank wound, two-layer	N
Honeycomb	D	Bank wound, three-layer	G
Two-layer	E	Bank wound, four-layer	H

TABLE 2.—*Key for test coils, using binder*

Binder used	Symbol	Binder used	Symbol
Shellac	K_{28}	Spar varnish	P_{28}
Commercial insulating varnish A	L_{28}	Collodion	Q_{28}
Paraffin	M_{28}	Commercial insulating varnish B	R_{28}

Detailed information on all coils is given in Table 3. The resistance at 1 kc is, for the coils used, practically equal to the direct-current resistance. For this reason the direct-current resistance is utilized for evaluating the ratio $\frac{L_o}{R_o}$ at 1 kc.

Coil Q:
http://www.lessmiths.com/~kjsmith/crystal/coilq.shtml
Kevin Smith

Introduction:

I have been building and studying crystal radios for some time now and slowly begin to learn a few things about these marvelous sets. In this section I begin my exploration of coil, coil quality and that mysterious dimensionless factor, Q... This page thus is a bit preliminary as I have not yet begun any measurements to determine the Q of my coils. Please bear with me.

My purpose here is to present some facts and data that has resulted from my explorations of the web. I have often wondered at what the quality factor of my coils should be and as often realized that I really do not have any expectations as to what is possible. Now, having dome some research, I can with some confidance say that this is solved. Coils as used in crystal radio broadcast band reception typically employ coils with Q factors ranging from 100+ (pretty lousy) through the several 100's (decent) and on up to 1000 or more for those remarkable Big-Litz wonders ($$$). Knowing the expected (or actual) Q of your coil is important in so far as it impacts the choice of diode to be used in the set. On my page of Diode Calibration I present a summary graphic which indicates how the diode Rd value relates to the tank parallel resistance Rp. This Rp in turn is a function of the coil Q. Schezzam! So here we are.

In your set construction, with a good effort and good engineering practice one can easily expect to wind a solenoid coil in the Q = 200 range without much trouble, even with a

---

7. All the insulating materials which were used as binders caused very slight increases in the resistance of the coils. Collodion seems best, and also has the inherent advantage of drying rapidly after application to the coil. This is of especial advantage in the construction of a bank-wound coil.

WASHINGTON, May 25, 1925.

V. SUMMARY

1. The various experimentally obtained curves given in this paper can be used as design bases for comparing coils of six types for any frequency in the broadcast range. For these data to apply it is necessary that the coils be constructed in accordance with the information given in Table 3. The coil dimensions are such that the coils are applicable to modern broadcast reception. A statement of the important characteristics of coils is given in the introduction.

2. The curves shown in Figures 9 and 11 give the changes of resistance and of $\frac{L}{R}$ with frequency. High values of these ratios do not in all cases correspond to high values of radio-frequency resistance. In some cases, for instance, a particular coil has a relatively high value for $\frac{\Delta R}{R_o}$, although the actual radio-frequency resistance is not large, because the direct current resistance is comparatively low.

3. The curves of Figures 8 and 10 give the actual radio-frequency resistance and ratio of inductance to resistance at various frequencies.

4. Of the coils measured the loose basket weave coil and the single-layer coil, and next to them the radial basket weave coil wound on hard rubber, have the lowest radio-frequency resistance. The four-layer bank-wound coil and the honeycomb winding have the highest resistance. This can not, however, be generalized to other frequency ranges. For instance, for low-frequency sets (20 to 100 kc) the multilayer bank-wound coil and the honeycomb coil have relatively low resistance, and besides are good coils mechanically while the loose basket weave coil has no special advantage and the single-layer coil can not be used on account of excessive size.

5. There appears to be little reduction of resistance at the lower frequencies in spacing the turns, so that the advantage of getting a smaller resistance is small compared with the disadvantage of requiring a coil twice as long.

6. The use of Nos. 32–38 litz gives coils of somewhat lower resistance than coils wound with solid wire of the same cross section. No. 24 AWG solid wire has less resistance than No. 28 wire, and No. 16 wire for a certain range has less resistance than Nos. 24 and 28 wire. If solid wire is used it does not appear necessary to use wire larger than No. 24 AWG. This conclusion can not, of course, be extended outside the broadcast frequency range; for instance, No. 16 solid wire would be better for frequencies above 5,000 kc.

---

coil in comparison with an ordinary three-layer coil. Figure 4 illustrates the method used in making the "narrow basket weave" coil, in which the coil is built up along the pins, which are removed after the coil is finished. Figure 5 illustrates the method used in winding the " loose basket weave" coil, which requires a pair of pins for each corner. A spacing of 10 mm between the two pins of a pair was

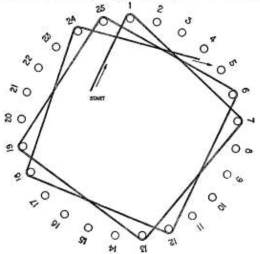

FIG. 4.—*Narrow basket weave. Four diagonal retarded winding (using 25 pins set on a circle. Coil builds up along axis)*

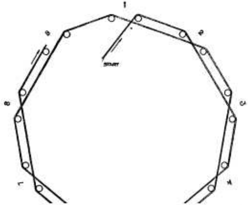

FIG. 5.—*Loose basket weave. Nine diagonal alternating winding (using nine pairs of pins set on a circle. Coil builds up along the axis)*

used. Figure 6 shows the method used in making the "honeycomb" coil. The zigzag winding is illustrated by the view of the entire cylinder surface. The winding is built up along the radii of the coil.

IV. RESULTS

The results are exhibited in graphical form. Figure 7 gives curves for the apparent self-inductance of the various test coils as a function of frequency. As on all curve sheets, the dotted curves indicate the different coils using No. 32–38 litz. It is seen that the "loose basket weave" type of coil and the "single-layer" coils give the lowest apparent inductance over the entire range of broadcast frequencies (500 to 1,500 kc). This indicates that the coil capacity is comparatively low, while the ordinary two-layer coil (E_{28}) acts more or less like a condenser, since the coil capacity is exceedingly large.

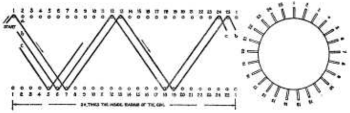

FIG. 6

Honeycomb coil. Four diagonal retarded winding (using 25 pins. Coil builds up along radius) *Cross-section of winding frame with the 25 pins*

Figure 8 gives the curves for the radio-frequency resistance. It is seen again that the values of the resistance vary greatly. Naturally, the ordinary two-layer coil (E_{28}) has very large radio-frequency resistance within the broadcasting range. Though its direct-current resistance is only 2.75 ohms, the effective resistance at 500 kc is 162 ohms, at 580 kc it is 465 ohms, and at 748 kc it is 1,800 ohms. The resistance increases very rapidly until it is mostly due to the dielectric resistance across the insulation between the layers. A three-layer coil wound in the ordinary way (ordinary multi-layer coil) and adjusted, like all coils discussed in this paper, to 291 microhenries at 1 kc has a radio-frequency resistance of several thousand ohms at a frequency as low as 400 kc.

Figure 9 gives the curves for the ratio of the increase of the radio-frequency resistance over its direct-current value to the direct-current value. It is seen that the loose basket weave and the single-layer coils have low values; next comes the radial basket weave coil,

---

TABLE 5.—*Variation with frequency of radio-frequency resistance (in ohms) for different binders*

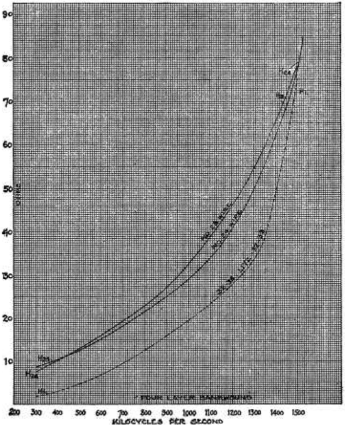
1,500	14.2	14.4	15.9	16.4	17.2	18.5



some cases the effective resistance of a coil using a binder came out smaller by a fraction of an ohm than for the coil using no binder. The binder seemed to make an accurate resistance adjustment more difficult.

3. EFFECT OF BINDER ON THE EFFICIENCY OF COILS

The binders used in this test were each applied to a single-layer coil, and just enough of it to cover the entire surface. The varying nature of the different binders probably resulted in different thicknesses. The coils in every case were dried thoroughly. The measurements were a little difficult when a binder was used, even though great care was taken to have the binder dried. For instance, in

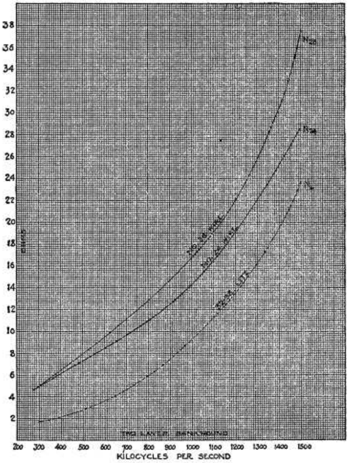

FIG. 17.—*Radio-frequency resistance of two-layer bank-wound coils*

Table 4 shows that it is not so serious to have a few strands broken, since the radio-frequency current apparently finds its way back across the strands. Even if, say, six strands are broken, the radio-frequency resistance is 3.4 ohms as compared with 3.1 ohms for perfect strands.

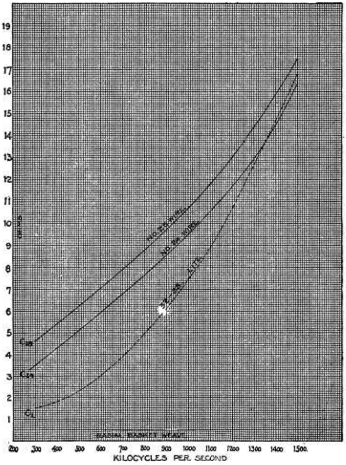
Litz used is Nos. 32-38 and has 32 strands of No. 38 AWG enameled wire braided together.



convenient use in receiving sets. Figure 12 shows a single-layer coil the turns of which are spaced by a distance equal to the diameter of the wire. There seems to be no material reduction in resistance except at the higher frequencies.

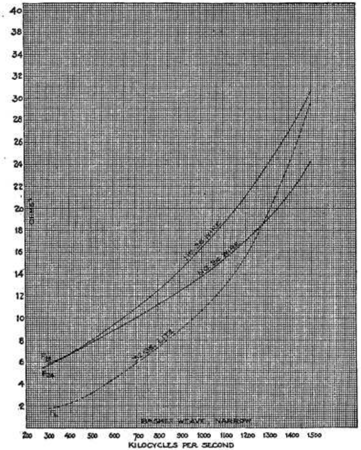


FIG. 14.—*Radio-frequency resistance of narrow basket-weave coils*

2. EFFECT OF BROKEN STRANDS IN LITZ WIRE

The question is often asked concerning litz wire as to the effect on the resistance of some of the strands being broken or not connected at the respective ends.

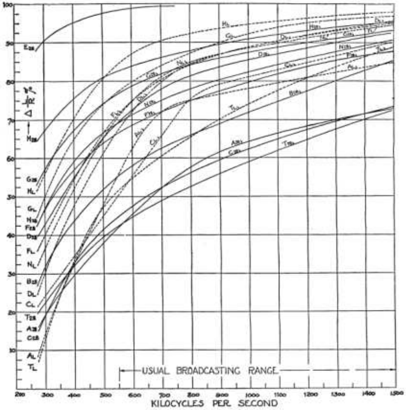

FIG. 11.—*Percentage decrease in the ratio of inductance to resistance below the value at 1 kc*

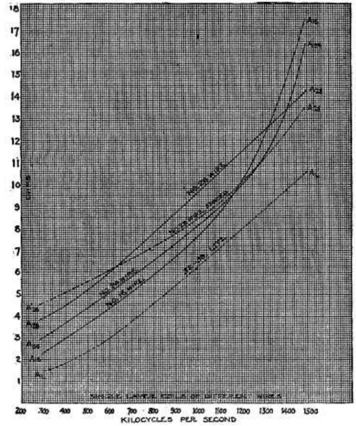
50081—25. (Face p. 658.) N

using hard rubber for the core, while the four-layer bank wound, three-layer bank wound, and the honeycomb coils show considerable percentage increases.

Figure 10 gives the curves for the ratio $\frac{L}{R}$. It is always smaller than the ratio $\frac{L_o}{R_o}$ at 1 kc. Since the apparent inductance and the radio-frequency resistance increase with the frequency, this ratio in certain cases has only small changes although both L and R are changing rapidly. Nevertheless, these curves show about the same comparisons as the resistance curves.

Figure 11 gives the curves for the percentage decrease in the ratio $\frac{L}{R}$ at different frequencies.



1. EFFECT OF THE KIND OF WIRE ON THE RESISTANCE OF A COIL

In order to show the effect of the size of the wire, curves for the resistance for No. 28, No. 24, and No. 16 d. c. c. are plotted and compared among themselves and against No. 32–38 litz. These comparisons are shown in Figures 12 to 19.

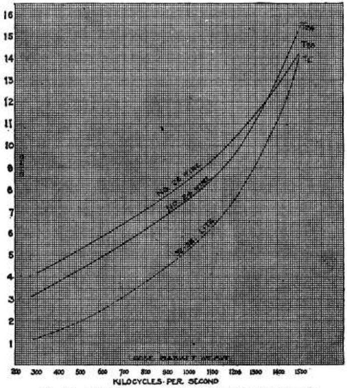


Fig. 13.—*Radio-frequency resistance of loose basket-weave coils*

It will be noted that in all cases litz, which corresponds roughly to No. 23 solid wire as regards its cross section, had the lowest effective resistance. If solid wire is used, it appears unnecessary to use wire larger than No. 24, although No. 16 gives, for the lower frequencies, resistances which are slightly lower. Such a large size of wire would, however, make the winding of certain types of coils more difficult and the size of the finished coil too large for

NOTES:

NOTES:

INTRODUCTION

This handbook stems from my studies of set resonance, LRC circuits and the quality of the tank components. My measurements on coil Q led me to believe I need to take the other components of the tank more seriously, noteably the capacitor and even the wire from which the coil is wound. In many radio articles I have read the Q-factor of the tank variable capacitor is generally assumed to be very high. High enough as to be disregarded as a significant contributor to the tank Q. Recent discussions on the Radio Board suggest that this may not be the case but in fact contribute significantly to tank resistive losses.

The first several chapters of this handbook then address capacitors, both from a general standpoint and then from the question of capacitor losses. Several articles on measurement techniques are included although it is noted that the capacitors they address appear to botton out at the 1uF range and do not include the smaller MW band picofarad world. Also they seem to be aimed at electrolyte caps. Still, this should stimulate the gray matter and suggest possible attack angles on the problem for crystal radio.

Next I address the question of wire resistance, primarily with a couple handy tables of wire data. High-End coils are wound from litz wire and so this was a partictular focus as I do not know much about this type of wire. A good page on litz wire resistance and data required to make your own calculations should help greatly, followed by papers on general litz considerations. With this edition I hope I will have covered most technical/theoritical aspects of crystal radio and can get back to the happy job of design and construction, this time with a more thorough understanding of what the heck I am up to.

Of general note, the web is a marvelous source of data and information. Many long-time crystal set builders, and many others have created dedicated sites to disseminate information and resources, to share their creations and knowledge. I am eternally in your debt. All of the material in this handbook is copyright for which I have not sought permission. Therefore this is not presented for publication or copy. It is only my personal resource. I encourage anyone finding this copy to pursue ON THE WEB the web pages identified within. I include the name of the author and web address of each section. I wish to sincerely thank every author presented for their excellent pages and ask forgiveness for my editing into this handbook.

to adopt wires of Litz construction to reduce the change in internal inductance and resistance as a function as frequency. However it would still probably be good advice to ensure that each wire bundle was of reasonably large diameter, and the bundles were closely spaced.

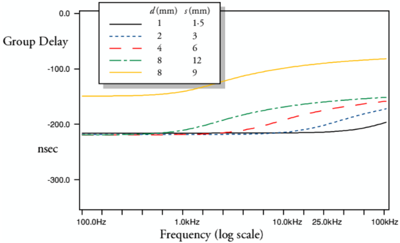

Figure 14 Delays as affected by wire diameter

Figure 14 plots the group delays for the same cables as were used as examples for Figure 13. Looking at these it can be seen that for the examples which share the same value the smallest diameter tends to push the variation in delay as a function of frequency up into the ultrasonic range. Hence a small diameter might be desired if this result is wished. However, by using the thickest wires with a closer spacing we obtain the result shown with the orange line. This reduces the overall level of delay.

In practice it is questionable whether delays of the magnitudes shown would ever be audible. If so, the general advice would seem to be to choose reasonable large diameter wires with a close spacing in order to minimise the effects of resistance and inductance. Since the characteristic impedance of the cables tend to be low compared to those of a typical load the cable series resistance and inductance seem to have far more effect than cable capacitance. This being so, it is the cable resistance and inductance which we should regard as the primary threat to reliable signal transfer. If the change in group delay over the audio band is felt to be significant, a suitable remedy would be

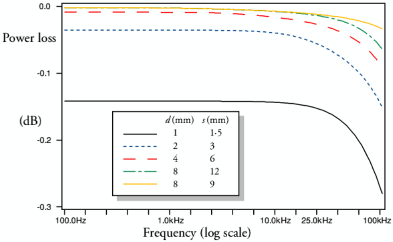

Figure 13 Signal loss as a function of wire diameter

Having examined the effect of varying the wire spacing we can now look at the effect of the choice of wire diameters. Figure 13 shows the power loss as a function of frequency for our standard twin feeder, but using various wire diameters and spacings. Four of the plotted lines have the same wire diameter (d) to spacing (s) ratio. This is to ensure that they all actually have the same characteristic impedance and hence the same nominal inductance and capacitance per length. The variations between these four examples are therefore only due to changes in the internal resistance and inductance of the wires.

Comparing the four plots which share the same value we can see that the lowest losses occur when the wire diameter (and hence spacing) is largest. This seems to clash with the desire to choose a low wire spacing. However the final plot (shown as a solid orange line) is for the largest wire diameter used for the previous four examples, but with a much smaller spacing. This reduces the inductance and hence reduces the level of high frequency power loss.

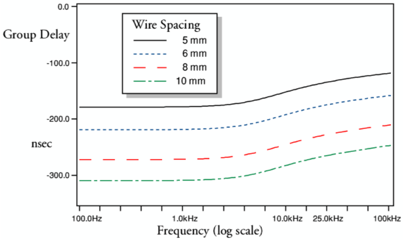

Figure 12 Delays as affected by wire spacing

Figure 12 shows the time delay plots for the same set of spacings, etc, as used for Figure 11. As we would expect, as the spacing is increased and the cable inductance rises, the delay also rises. From the results shown in Figures 11 and 12 we can reasonably expect that we can generally hope to reduce the high frequency losses and overall group delay by choosing a small wire spacing and minimising the cable inductance.

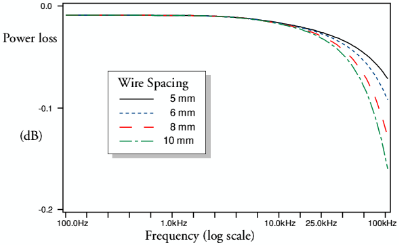

Figure 11 Signal loss as a function of wire spacing

Figure 11 shows the effect of various choices of wire spacing, with a common wire diameter of 4mm (i.e. as previously, a wire radius of 2mm). Note that this has a different vertical scale to earlier power/frequency plots to accommodate the greater losses produced by the wider-spaced cables. Looking at the results we can see that the effect of moving the wires apart is to increase the relative loss at high frequencies. This is simply a consequence of the increase in wire spacing producing a corresponding rise in the cable's inductance per unit length. The combination of the cable inductance and the load resistance act as a conventional low-pass filter. Since the wire diameter is the same for all the lines shown in figure 11 they all have the same value of wire internal impedance.

Secondly, the above assumes we have maintained the diameter of the wire when changing to a lower conductivity material. As we can see from figure 9 this would produce quite high signal losses, and would make the response more sensitive to any frequency dependence of the load impedance.

Thirdly, we can interpret the reduction in the dependence of the delay upon frequency as being due to the relatively high cable resistance ‘swamping’ the inductance. i.e. the wire resistance is now so high that the cable/load system begins to look more like a simple resistive potential divider with a relatively negligable inductance.

In practice we would probably choose to increase the wire diameter to keep down the overall level of wire resistance. This increase in wire diameter would also increase the value at any frequency, thus lowering the frequency at which phase changes may occur.

7. Effects of wire diameter and spacing

For all the examples considered so far we have used the same values of wire diameter and spacing. This has allowed us to compare various choices of conductor, etc, on a ‘like for like’ basis. In practice, however, one of the most common types of variation from cable to cable is in the choice of the diameters of the wires, and the spacing between them. We can now use a convenient standard material (Copper) and explore the effects of varying the spacing and diameter of the wires. As before we will assume a 3 metre length of twin-feeder, and an 8 Ohm resistive load as the standard for the purposes of comparisons.

Capacitor Theory

https://ece.uwaterloo.ca/~lab100/ls1notes.pdf

Any arrangement of two conductors separated by an electric insulator (i.e., dielectric) is a capacitor. An electric charge deposited on one of the conductors induces an equal charge of opposite polarity on the other conductor. As a result, an electric field exists between the two conductor surfaces and there is a potential difference between them. The electric field anywhere between the conductor surfaces is directly proportional to the magnitude of the charge Q on the conductors. And the potential difference V is also directly proportional to the charge Q. The ratio Q/V is thus a constant for any electric field distribution as determined by the shape of the conductors, the distance of separation, and the dielectric in which the field exists.

The ratio Q/V is called the capacitance, C, of a particular arrangement of conductors and dielectric. Thus, C = Q/V, where Q and V are in units of coulomb and volt. C has the units farad (F).

$$C = \frac{\varepsilon_r \quad \varepsilon_o \quad A}{d} \qquad (F) \qquad (farads)$$

The simple theoretical expression for the capacitance value of a parallel plate capacitor is where

A = plate area [m2] = cross section of electric field,

d = distance between plates [m],

Eo = permittivity of free space = 8.854 x 10-12 F/m and

Er = relative permittivity of the dielectric between the plates [dimension less].

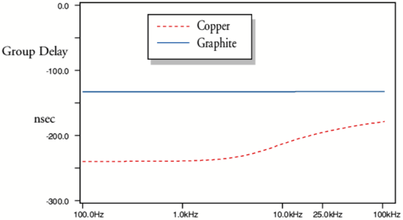

Figure 10 Delays of Graphite and Copper

Figure 10 shows the phase delay behaviour of graphite and copper. In this case the behaviours of the two materials are clearly very different. At low frequencies the inductance of the wires is not dependent upon the resistance level. Hence we do not see the ‘scaling’ effect we encountered when looking at signal losses which there tends to offset the reduction in at any frequency produced by the lower conductivity. From figure 10 therefore we can say that the variation in phase delay with frequency in the audio band is much smaller with graphite than with copper. The graphite also shows a lower overall delay as well as better uniformity. Hence low conductivity materials may be useful if we wish to reduce differential phase/time effects.

However we must draw such a deduction with care for three reasons.

Firstly, the phase changes at audio frequency are very small, even using copper. It is therefore questionable that they would be audible.

$$\frac{100R_0}{100f_0} = \frac{R_0}{f_0}$$

i.e the same in both cases!

This example is not exact and the behaviour is more complex than described here. However this example shows why it turns out that both materials show a noticeable change in signal loss at much the same frequency. Hence for a given wire diameter changing the choice of material has much less effect upon the frequency dependence of the signal loss than we might expect. In fact, we have already seen this to a lesser extent. If we examine the earlier results for fill factor we can see that the main effect of a fill factor of less than unity is to displace the loss curve to a higher or lower overall loss, not to changes its shape.

Using the same wire diameter, etc, as before, do see a marked increase in the low frequency loss due to the lower conductivity. This is simply due to the wires having a much higher d.c. resistance when we change to a material like graphite which has a relatively low conductivity. In practice the level of loss in the example chosen here (around -5 dB) would be far too high for a loudspeaker cable. When using such a lower conductivity material we would therefore probably choose to employ wires of much greater diameter (and hence cross-sectional area) to ensure a low level of loss. However it should be noted that this will mean a change in the value at any given frequency and alter the cable’s behaviour in other ways.

This calculated value is based on the assumption that the charge density on the plates is uniformly distributed. In practice there is always a concentration of charge along the edges. This charge concentration is at the sharp corners of the plates. Thus for a given voltage, the actual total charge is always greater than the theoretical total charge.

Practical Capacitor Model

The low frequency lossy model is introduced to allow you to measure capacitance with a
capacitance measuring bridge instrument.

Discrete component measurements and models of the physical capacitor need to be considered here. Consideration of a finite subdivision of the physical device may assist in arriving at a lumped discrete equivalent circuit model of the practical physical device (ie: a capacitor).

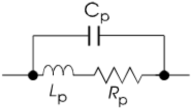

**Figure 1.
Capacitor Model
With Parasitic L & R**

First consider the physical device, the capacitor. We have two conducting surfaces separated by some distance. Hence a defined capacitor . Assume there is a voltage applied to the capacitor. The dielectric has some loss1 and will conduct a small urrent. One can consider this as a distributed loss within the length of the dielectric material between the two conductors. Hence a resistance in parallel with the capacitor.The lossy dielectric has length. Hence one could conceive a distributed inductance2 in series with the distributed resistance. Hence the inductor as shown in figure 1.

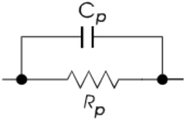

Figure 2. Capacitor Model With R Only

At very low frequencies (say 1 kHz) the parasitic inductance can be ignored3 for the parallel plate capacitor you will be using. Hence the model will only have the capacitor and resistor in parallel as seen in figure 2.

In this experiment the parallel model resistance is very large. Hence the dissipation of energy is small. The resistor will dissipate very little energy. Thus we will have a capacitor with a low dissipation factor, D. One can calculate the resistance value knowing the value of D measured after balancing the bridge.

The capacitance measuring bridge has to be adjusted so that both the capacitance and the resistance of the practical model are balanced. This is the reason for adjusting both the CRL and the DQ dials of the Capacitance Measuring Bridge.

1) The dielectric has a finite resistivity, so when an electric field is across it, a small but finite electric current flows through it. This current, or charge flow, is referred to as a loss (from what an ideal device would do).
2) Because the plates of the capacitor are conductors with current flowing through them, they have a small amount of self inductance.

---

around 0·05dB greater than the loss at d.c. This is lower than the the drop of around 0·1dB we would obtain using materials like copper, but the improvement is surprisingly small given the factor of 1000 in conductivity.

To understand this behaviour we can consider an example where we have two rods of material which have the same diameters and lengths. One material has a conductivity which is 100 times lower than the other. As a result the end-to-end d.c. resistances of the rods also differ by a factor of 100. The frequencies at which the a.c. resistances of the rods double due to the effects of finite skin depth (internal impedance) also differ by a factor of 100. We can now define a specific value of the ratio of skin depth to diameter (and hence) which is the value for which the a.c. resistance is double the d.c. resistance. For the rod of lower conductivity material this value of occurs at a frequency 100 times higher than for the rod of higher conductivity material.

As a result of the above we would expect the effect of skin effect to be shifted up in frequency by a factor of 100 when we change from the higher to the lower conductivity rod. However, we must then also take into account another difference which turns out to be significant. From the above we can say that the higher conductivity rod can be said to have a d.c. resistance, , which increases to at a frequency we can label . The lower conductivity rod will have a d.c. resistance of which rises to at a frequency . Another way of looking at what happens is therefore that the higher conductivity rod changes its resistance by an amount when we change the frequency by an amount . Whereas the lower conductivity rod changes resistance by when we change the frequency by . This means that in each case the overall rate of change of resistance as we change the frequency will be

6. Effect of low conductivity material

Having noticed the effect of the relatively low conductivity of aluminium some manufacturers and writers have argued that it would be better to deliberately use a material with a particularly low conductivity. Carbon (graphite) has frequently been mentioned in this context. To estimate the effect of using such a material we can now use figures 9 and 10. These show the relative loss and phase delay for the two materials and our standard example of cable.

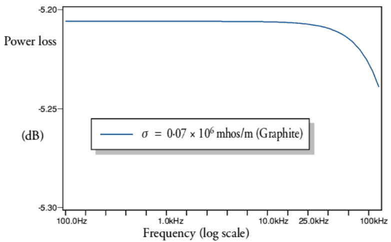

Figure 9 Signal loss for Graphite

Figure 9 shows a result which at first examination seems strange. The graphite has a conductivity around three orders of magnitude lower than that of copper. The skin depth in graphite at any frequency is therefore around 30 times greater. For a given wire diameter this might lead us to expect any increase in loss as the frequency rises to be shifted up to much higher frequencies in graphite than in copper. Yet figure 9 does not seem to show this. The increase in signal loss at 100kHz is

3) The change in current and direction is so slow, the self inductance effect is almost too small to measure.

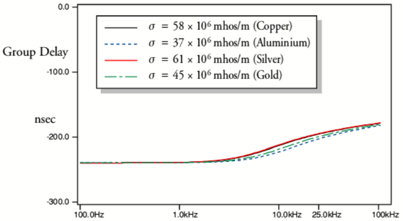

Figure 8 Effect of material upon delay

As with variations in fill factor, the variations between the materials used as examples here seem quite small. Hence it is not obvious that changing, say, from copper wires to silver ones of the same diameter and spacing is likely to produce an audible change as a result of differences in the internal impedance of the wires. Curiously, although aluminium is generally regarded as a 'poor' choice for wiring in audio systems, its relatively low conductivity does mean that the effects of internal impedance tend to occur at slightly higher frequencies than copper.

It is interesting to note that the nominal behaviours of copper and silver are quite similar compared to their difference from aluminium or gold. However it is worth bearing in mind that most of the metals used for wires are far from being of elemental purity. This means that the actual conductivity of a wire may differ by perhaps 5% or more from the standard values assumed for the above calculations. This in itself is unlikely to be significant compared to the much larger range in conductivities for the materials used here as examples.

5. Effect of material conductivity

We can now examine the effect of various choices of conductive material. Figure 7 illustrates the effect of using four different choices of metal for the wires. The same wire diameter and spacing is assumed as previously, and the fill factor is assumed to be unity.

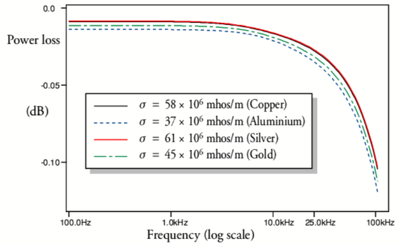

Figure 7 Effect of material upon loss

Figure 8 shows the related results for signal delay values.

What is the best variable capacitor for my crystal radio?

By Dave Schmarder

http://makearadio.com/misc-stuff/capacitors.php

This is a question that has been asked of me many times. It would be easy for me to just say, "Just buy some holy grail capacitors.". Unfortunately, they are not so common anymore, and when you see how much they cost at the large auction venue, you'll forget about the high cost of the litz wire that goes with them.

The purpose of this paper is to discuss various types of variable capacitors, showing their good and bad points. I have come up with some answers that I have not seen discussed elsewhere. Perhaps this work will help you find the right variable capacitor for your radio.

This paper deals nearly exclusively with a crystal radio detector unit in a two section radio. Discussion of an antenna tuner section can be found on my antenna tuner page.

Before we get down to the nitty-gritty brass tacks of the actual capacitors that you should get, let's set the basics for this page. First, anyone that wants to build a dx set should visit the crystal radio DX'ers best friend, Ben Tongue's website. Specifically his paper dealing with variable capacitors as used in crystal sets. In his article 24, section B1, his charts plainly show the difference between a holy grail and an everyday capacitor.

One even wonders how a crystal set works with such a lousy capacitor. Well, it really isn't that bad. But with losses highest at the high end of the band, plus the very squeezed tuning (10% of the capacitor rotation covers 30 to 40% of the

---

Looking at figure 5 we can see that changing the fill factor from being unity down to 0·7 has a surprisingly modest effect upon the signal loss behaviour.

Figure 6 shows the delay behaviour for the same set of fill factor values.

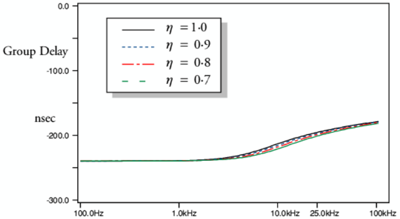

Figure 6 Effect of fill factor upon delay

Again, the changes are relatively modest. On the basis of these results it does not seem as if the fill factor value of stranded wires is likely to have a noticeable effect for twin feeders of this type. That said, it may be more significant for wire diameters and spacing other than those used for this example. More generally, however, it seems that a Litz construction (with the strands individually stranded) is probably usually required for multistranded wires to have audio properties that differ noticeably from solid wires. That said, multistrand is often physically more flexible, and may be easier to connect, so may be more convenient than solid-core for other practical reasons.

Again it is not clear that this would be noticeable in a practical situation.

4. Effects of fill-factor

For the sake of example, the cables considered until now were assumed to be made of copper with an effective fill factor value of unity. To assess the typical effects of a change in fill factor, or of the chosen conductive material, we can recalculate the behaviour of a cable similar to that used before, but with various fill values or materials. As before we therefore assume a 3 metre length of twin-feeder with 2mm diameter wires spaced with their centers 6mm apart.

Figure 5 shows the power loss for four differing values of the fill factor, using copper wires.

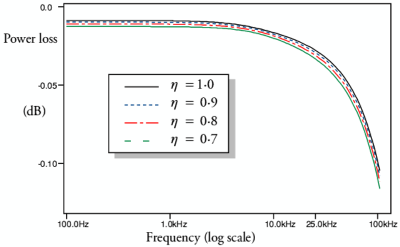

Figure 5 Effect of fill factor upon power loss

---

frequency range), there is a lot of bad karma at the high end of the band.

Below are some examples of capacitor traits. They are not in any particular order of importance or the goodness of one capacitor over another.

A variable capacitor is made up of two major sections, a stator or stationary part, and a rotor or moveable section. These sections are made with plates, also called vanes or blades. The frame is usually connected to the rotor and is one connection of the capacitor. There are some instances where the rotor is isolated from the frame, but not too often.

Dielectric

This is the material that separates the stator plates from the rotor plates. An air dielectric is most common, and is very low loss. Air has a standard dielectric constant of 1.0. Sometimes other materials are placed between the rotor and stator plates, mainly so the plates can be closer together. This allows for a smaller capacitor size, but it is at the expense of higher losses. I like using air capacitors the best.

Insulators

Insulators are the non-conducting material that holds the stator plates to the capacitor frame. The insulator material is considered by most builders the prime criteria in selecting a good capacitor. Two major types of insulating materials used are ceramic and phenolic. Ceramic is consider the very best and the only thing to use in a dx crystal set.

However, new ceramic insulated variable capacitors are expensive. For less aggressive radios, and very aggressive budgets, phenolic is the choice.

Plate Plating

Some of the variable capacitors that you see will have a silver plating. Ben warned us in his article that what appears to be silver plating might not be. The new capacitors sold have bare aluminum plates. They are higher resistance than the silvered plates. Of all the capacitor spec's, this is the least important. But most of the older capacitors that have ceramic insulators will also have a better plating.

Wiper Arms

The wiper arms are those little springy thin pieces of metal that attach to the frame and contact the rotor. Variable capacitors are rated by the number of wipers and how much surface area is in contact. The tightness of the contact should also be considered. Tight is good.

Inexpensive capacitors sometimes have no wiper arms. While they do work, their use in a good crystal set is discouraged. Other cheaper capacitors have just one small wiper at the back frame. The contact area is small, and the contact pressure is fairly light. These are ok for TPT sets. (Radios that are low performance because the builder uses coil forms made with cardboard Toilet Paper Tubes.)

The maximum number of wipers is determined by how many frame surfaces are reachable. In a single gang capacitor, two, one at the front and one at the back is the maximum. In a two gang, it's four (front, back and two in the middle), and so on.

Most hobbyists don't consider the wiper arm quality when they are looking for the capacitor for their dream radio. I consider wipers to be almost as important as the insulator material. I have tested phenolic insulator capacitors that had very nice

---

$$v = \frac{c}{\sqrt{\varepsilon_r}}$$

where is the velocity of light in vacuo, and is the relative permittivity. Here so we would expect a velocity of around 2· 44 × 108 m/s. Hence we might expect a propagation delay when using 3 metre cable of only around 12 - 13 nanoseconds. Yet we see values over ten times greater than this.

The reason for this discrepancy is that microwave/RF engineers usually arrange to match the source and load impedances to the cable’s characteristic impedance. This is far from being the case here. The load resistance is 8 Ohms, but the cable has a characteristic impedance of around 75 Ohms. Since the cable is also very ‘short’ in terms of the signal wavelengths it primarily acts as an inductor and resistor placed in series with the ‘low’ load impedance. At low frequencies the signal delay is therefore approximately equal to which – ignoring internal effects – in the example equals around 164 nanoseconds. Hence the group delays we see are in broad agreement for what we would expect as a result of cable inductance in this example. The dashed line (equivalent to Litz wire) shows a value of 164 nanoseconds as internal inductance has been suppressed. This indicates that although the solid conductor (or a similar stranded wire) have a value of around 240 nanoseconds at low frequencies only around 80 nanoseconds of this is due to the wire’s internal inductance.

Despite the above, to an acoustic engineer the delays seem very small. Since sound propagates at a velocity of around 330 m/sec it will only travel around 16 microns in 50 nanoseconds. In effect, therefore, the above differential group delay is equivalent to a sound source that seems 16 microns nearer at high audible frequencies than at low audible frequencies.

lines we can see that the internal impedance causes the group delay to depart from being uniform. If no ‘skin effect’ were present the group delay would be almost steady at 164 nanoseconds across the whole band plotted. However when the internal impedance of the wires are taken into account the group delay varies from around 240 nanoseconds at low frequency, to around 212 nanoseconds at 10kHz and around 195 nanoseconds at 25 kHz. The effect of the internal impedance is therefore to produce a differential group delay of around 50 nanoseconds across the audio band. Interestingly, high frequencies will tend to arrive slightly earlier than low frequencies.

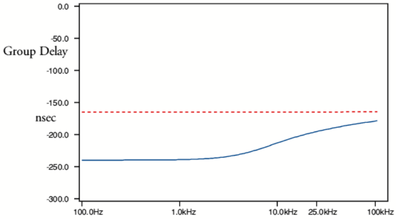

Figure 4 Group delay versus frequency

Curiously, the above time delay values can be seen as ‘large’ or ‘small’ depending upon your starting point. To a microwave/RF engineer with experience of transmission lines a delay of around 200 nanoseconds seems oddly large for a twin feeder only three metres long. Since we are assuming that no magnetic materials are present and a twin feeder propagates a TEM wave we might expect a propagation velocity of

---

wipers and while they didn't test as well as ceramic types, they were still very decent.

Capacitance Minimum to Maximum Ratio

Here is something that almost nobody considers when buying their capacitors, until the builder tries to tune the entire band with a low maximum to minimum capacitance ratio and finds out that it doesn't work. The US-Canadian broadcast band is from 530 to 1710 kHz (while the US is 540 - 1710 and Europe only goes to 1606 kHz). This means that if you are going to tune the entire band, without switching in additional capacitance or with coil taps (yeech), close attention has to be paid to the maximum to minimum capacitance ratio.

An example of a capacitor that will not tune the entire MW band in one swoop is a capacitor that is available on the surplus market. This capacitor has everything that one would want in a capacitor, except a good maximum to minimum capacitance ratio! A picture of it is shown below. Each section measures from about 300 to 35 pF. This is ratio of about 8.6:1. The medium wave band at my location needs a total ratio of at least 20:1 if it is expected to tune without band switching. This includes the distributed capacitance of the coil, and the diode input. At 20:1 there is very little leeway and the coil has to be constructed with extra care. The cheap capacitors fall well within this range, as they have a ratio of about 24:1.

The way you can tell about a capacitors ratio at a glance is to look at the plate structure. If you see a many plates and they are small, this means that the ratio is low. This is because when completely open, the capacitor still has a fair amount of surface between the plates.

Capacitor Frequency Linearity

Those of you that have tuned a radio using a capacitance linear capacitor such as the inexpensive ones mentioned earlier, noticed the top of the band dial squeeze. This is because the capacitance is linear to the rotation. If the capacitor shaft is rotated half way, the capacitance is approximately at half the total value. This means that the center of the dial is at around 800 kHz, about 370 kHz out of the total of nearly 1200 kHz that comprises the medium wave broadcast band. The other rotation half has to cover 3/4 of the band. It gets a lot worse the closer you get to the top of the band.

But what if you could move the capacitor 50% and have half of the band covered? This is what is called a straight line frequency capacitor. In practice having a completely straight line frequency capacitor is nearly impossible, but we can come close.

There are three basic types of capacitor construction. One is where the shaft is centered on the capacitor frame, right to left. The capacitor plates are semicircular. This operates as a straight line frequency capacitor (because if you plot the capacitance vs. the rotation, there is a straight line result).

Another type which was very popular in the old superhet tube radio days was with the shaft and plates offset from the center. These types can also have a modified plate shape, which produces a slight "S" curve when the capacitance vs. rotation is plotted. These, mostly dual gang capacitors are widely sold, but not as popular as the inexpensive single gang linear variable capacitors.

You can expect to pay twice as much for these as the inexpensive capacitors, but most have the advantage of a dual wiper, which lowers the losses. The tuning of this capacitor

Figure 3 shows the power loss in the cable as a function of frequency. The solid (blue) line shows the loss when the wire's internal impedance is taken into account. The broken (red) line shows the loss that would occur if we ignored the internal impedance. Hence the difference between the two shows the results in this case of 'skin effect'. In principle, the broken line shows what we might expect when using wires of 'Litz' construction with a fill factor approaching unity. The solid line shows what we might expect from either a solid wire or a multistranded wire of closely packed thin strands.

For the example chosen, at low frequencies the bulk resistance of the copper wire causes a power loss of around 0·008dB. At 10kHz the loss rises to 0·009dB if the internal impedance were absent, and 0·016dB with the internal impedance taken into account. At 25kHz these values rise to 0·012dB and 0·028dB respectively. Hence the change in relative signal level from near-d.c. to 25kHz, with internal effects taken into account is around 0·020dB. This is quite a small change so it is not obvious that it would be noticed in a practical audio system.

Figure 4 shows the group delay as a function of frequency. This measure is more convenient that plotting any change in phase since a propagation delay will manifest itself as a phase change that rises linearly with frequency. When signals have to propagate through a system the group delay is therefore a better indicator of any time domain effects that might alter the signal pattern. A uniform group delay value implies that all components will arrive with the same relationship as when they were transmitted.

As with figure 3, figure 4 shows two two lines, the solid (blue) one taking internal impedance into account, and the broken (red) line neglecting internal impedance. By examining these

For illustration we can use a case where we have copper cables (assume = 5·8 × 107 mhos/metre) which have wire radii of 2mm with their centers 6·5mm apart. We can also take as an example a twin feeder length of 3 metres. (i.e. 6 metres of wire, in total, in the circuit) and assume a nominal load of 8 Ohms. We can also assume a perfect voltage source and set the source resistance to be 0 Ohms. The cables are assumed to be insulated with a dielectric whose relative permittivity value is 1·5. Most practical dielectrics tend to have a higher value, but the effect is diluted since part of the surrounding E-field is in the air, so this value seems a reasonable one to assume for the purposes of an example.

The results obtainable for this situation are indicated in the following graphs. The dimensions chosen for the wires here are not meant to represent any specific cable, but seem typical for a relatively inexpensive form of wiring.

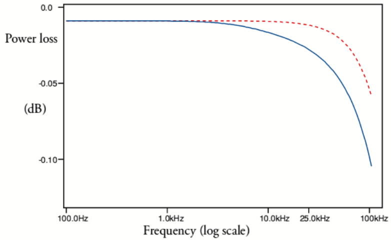

Figure 3 Power loss in transmission versus frequency

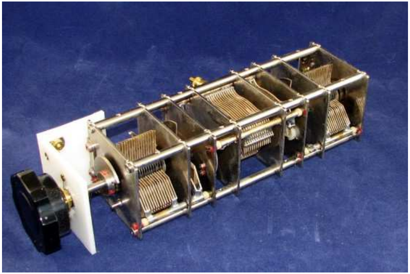
---

does help the high end of the band frequency crunch. It is at least tolerable.

The third type is a closer to a straight line frequency capacitor. This has highly shaped plates plus the offset shaft position. There is a much better frequency spread across the dial, especially at the top end of the band.

Insulator Loss vs. Capacitor Plate Loss Ratio

As Ben so clearly shows in his charts, as the capacitance is increased on a particular variable capacitor, the losses go down. In his example of the cheap capacitor, the losses go down by over a factor of 10 when the shaft is rotated to about 1/3 of the way up. The more expensive capacitor also trends up, but at less steep rate. This is because the losses of the dielectric and wiper arms are summed with the losses between the capacitor plates.
High quality capacitor with a lot capacitance minimum to maximum ratio.



This is the so called "waysalot" capacitor. I used a pair of these in my #75 dx crystal set. It is the best quality capacitor I have. This one has a vernier attached and is used as a test capacitor for determining unloaded Q of the coil under test.

The so called Holy Grail capacitor. The dream of every dx crystal radio builder.

conductor in each triangle is equal to . However the area of each triangle will be . Hence the fill factor will be approximately equal to

$$\frac{\pi}{2\sqrt{3}} \approx 0{\cdot}9069...$$

Real strands will tend to deform slightly when compressed and may not have perfectly smooth, circular cross sections. They may also not be perfectly packed. Hence we can expect the actual value of the fill factor to vary accordingly in practice. In Litz bundles the insulation layers on the strands will also move the conductors apart by a small amount, thus reducing the fill factor value. Usually, we can expect this effect to be small as the layer of insulation is likely to be very thin. In most cases we can therefore tend to assume that the fill factor is reasonably close to unity so this is a reasonable assumption for general analysis. That said, in some specific cases we can take stranding into account by modifying the effective conductivity by an appropriate fill factor value.

3. Twin Feeder Loudspeaker Connections – an example

These internal values can now be used when we wish to evaluate the effect of a cable upon the transmitted signals. We can treat the connecting cables as a form of transmission line, and modify the inductance and resistance per unit length to take the internal values into account. At audio frequencies the cables are normally many orders of magnitude shorter than the highest signal wavelength so it is reasonable to then use lumped values which just multiply the per-unit-length value by the chosen length. For the sake of example here we will consider loudspeaker cables nominally in the form of ‘twin feeder’. For a given cable length this means we must remember to double the values for internal resistance and inductance as a pair of wires are used.

illustrated in figure 2. This shows a close-packed array of strands, each of radius .

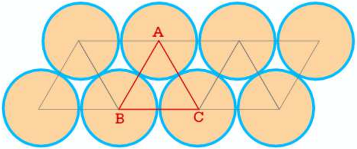


Figure 2 Cross section of a packed bundle of strands.

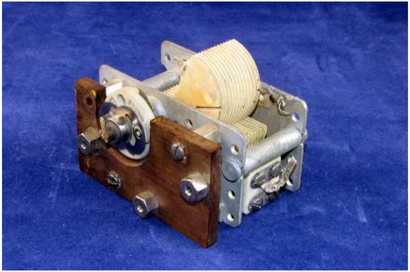
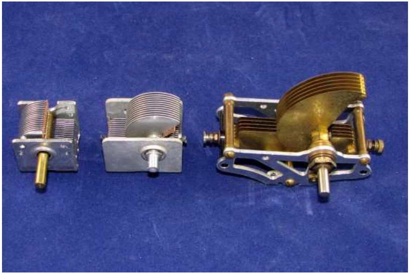
Since the strands all have a circular cross-section we find that even if they are tightly packed into a hexagonal array there will be spaces in between the places where they touch. Hence a bundle of small packed strands that are in electrical contact can be regarded as similar to a solid but which has some air inclusions which mean that overall wire cross section is only partly filled with conductor. Given a value for the 'fill factor', , (the fraction of the cross section which is filled with conductor) we can treat the wire as being equivalent to a solid conductor of the same wire diameter, , but having an effective conductivity of . Thus the main electronic effect of using a bundle of strands is to dilute the effective conductivity and lower its apparent value.

To estimate the value of the fill factor we can note that the array has a symmetry similar to a packed array of equilateral triangles whose sides all have a length of . Taking one of these elemental triangles we can see that it contains three 60 degree sectors of conductor. Hence the cross sectional area of



This is known as Holy Grail (everyone should bow and say "I'm not worthy, I'm not worthy"). This capacitor is about 475 pF can was removed from a high quality test instrument. If you can find one for less than seventy-five bucks, grab it.
Examples of capacitor styles with special attention to the plate shape.



Here are examples of three different variable capacitors frequency vs. capacitance plots. The one on the left is the inexpensive ones available everywhere. The shaft is centered left to right and the plates have a semicircular shape.

The middle one also has the semicircular shape, but the shaft is offset from the center of the frame and the plates. This offers better frequency linearity than the capacitor on the left.

Finally the capacitor on the right is a great example of a straight line frequency plot. The shaft is offset, and the plates are very long. It is only near the bottom of the tuning range is where a lot of capacitance is added with little turning of the shaft. This allows for a more even frequency spread across the tuning range.

Litz wire (as stranded but with insulation between the individual strands)

For solid-core wires the above analysis can be used immediately to compute the internal impedance and deduce the effects it may have in a given situation. For the stranded and Litz wires we need to take the stranding and the effect of inter-strand contacts or insulation into account.

Litz wires consist of a bundle of very thin, individually insulated conductors. The insulation ensures that the current flows in all of the wires in the bundle as the charge cannot migrate towards the surface of the bundle. The entire cross section of conductor bundle is therefore used by the charge transport. Provided that the individual strands are thin enough, the strands all have individual radii that are small compared to the skin depth at audio frequencies. Hence the overall properties of the Litz bundle tends to be similar to that of a single wire of the same diameter of the bundle but where ‘skin effect’ is apparently absent.

In practice, most of the multi-strand wires used for audio purposes have no insulation on the individual strands. This means they do not behave like a Litz wire. In stranded wires without insulation between the individual strands charge may cross from strand to strand. Hence current will tend to preferentially flow near the skin of the bundle of wires, just as it does with a single solid conductor of similar overall diameter. Hence when the strands are thin but in electrical contact with their neighbours we can expect the effect of internal impedance to be similar to that of a solid wire of a diameter similar to the bundle of strands. There is, however, one factor we should take into account. This arises when the strands do not ‘fill’ the bundle and their are air gaps. This is

The standard ‘h.f.’ approximation is that both and will be essentially equal to . However by inspecting the results shown in figure 1 we can see that it is possible to do better than this and a more reliable approximation would be

$$\frac{R}{R_0} \approx \frac{q}{2\sqrt{2}} + 0{\cdot}26 = \frac{r_0}{2\delta} + 0{\cdot}26 \qquad (9)$$

$$\frac{\omega L}{R_0} \approx \frac{q}{2\sqrt{2}} - 0{\cdot}02 = \frac{r_0}{2\delta} - 0{\cdot}02 \qquad (10)$$

This approximations are show in figure 1 by the broken lines. The approximation for is shown by a short-dashed red line, and that for by a longer-dashed green line. It can be seen that these approximations are likely to be reasonably accurate in the region .

2. Types of Wire

In general, electronic signals are conveyed using a ‘pair of wires’. These are used to form a closed loop (path) between the signal source and the load around which charge may flow. Broadly speaking we can then define a ‘cable’ to consist of a pair of wires. The most common forms of cable used in audio are ‘Twin Feeder’ and ‘Co-ax’. The basic properties of these are discussed elsewhere. Each of the wires may be a single, solid, length of conductor. More usually, however, each wire will consist of a bundle of conducting ‘strands’. Multistrand wires have properties which may differ from that of a single, solid wire of similar cross-section. We can therefore treat wires as falling into three general categories as outlined below.

Solid core (i.e. just one strand of conductor per wire)
Stranded wire (a bundle of thin strands of conductors)

Types of capacitor

From Wikipedia

http://en.wikipedia.org/wiki/Types_of_capacitor#Ohmic_losses.2C_ESR.2C_dissipation_factor.2C_and_quality_factor

Theory of conventional construction

Dielectric is placed between two conducting plates (electrodes), each of area A and with a separation of d

In a conventional capacitor, the electric energy is stored statically by charge separation, typically electrons, in an electric field between two electrode plates. The amount of charge stored per unit voltage is essentially a function of the size, the distance and the plates' material properties and the material, the dielectric, placed between the electrodes, while the potential between the plates is limited by the Dielectric breakdown field strength .

Nearly all conventional industrial capacitors except some special styles such as "feed-through capacitors", are constructed as "plate capacitors" even if their electrodes and the dielectric between are wound or rolled to a winding. The capacitance formula for plate capacitors is:

$$C = \frac{\varepsilon A}{d}.$$

The capacitance C for conventional capacitors increases with area A of the electrodes and with permittivity ε of the dielectric material and decreases with the distance d. The capacitance is therefore greatest in devices made from

---

results of doing this are illustrated in figure 1. These are plotted versus so that the relevant nominal skin thickness is also normalised in terms of the wire radius. The solid lines plotted show the relevant values calculated from the above expressions.

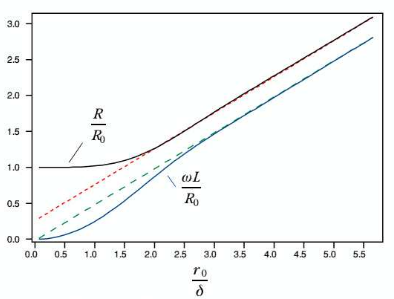


Figure 1 Wire impedance versus skin depth

Unfortunately, the expressions provided by A & S only cover the range for which roughly corresponds to . Above this value the Bessel functions become hard to evaluate and their combination tends to lead to a situation where a set of large values cancel to give a moderate result. Hence for computational simplicity we can use a simpler approximation for the situations where is 'large'. Here this may be defined as where this ratio has a value greater than 5.

The detailed analysis in Ramo leads to the following expressions which can be used to determine the relevant wire resistance and inductance per unit length for a conductive wire of circular cross section at frequencies above d.c.

$$R = \frac{R_S}{\sqrt{2}\,\pi r_0}\left[\frac{\mathrm{Ber}\{q\}\,\mathrm{Bei}'\{q\} - \mathrm{Bei}\{q\}\,\mathrm{Ber}'\{q\}}{(\mathrm{Ber}'\{q\})^2 + (\mathrm{Bei}'\{q\})^2}\right] \qquad (3)$$

$$\omega L = \frac{R_S}{\sqrt{2}\,\pi r_0}\left[\frac{\mathrm{Ber}\{q\}\,\mathrm{Ber}'\{q\} + \mathrm{Bei}\{q\}\,\mathrm{Bei}'\{q\}}{(\mathrm{Ber}'\{q\})^2 + (\mathrm{Bei}'\{q\})^2}\right] \qquad (4)$$

where

$$R_s \equiv \frac{1}{\sigma\delta} \quad ; \quad q \equiv \frac{\sqrt{2}\,r_0}{\delta} \qquad (5,6)$$

and is the ‘skin depth’ value which may be calculated via

$$\delta \equiv \frac{1}{\sqrt{\pi f \mu \sigma}} \qquad (7)$$

where is the signal frequency (as opposed to the signal’s angular frequency).

In fact, using the above expressions we can show that

$$\frac{R_s}{\sqrt{2}\,\pi r_0} \equiv \frac{R_0 q}{2} \qquad (8)$$

and specifying this factor in terms of and may be more convenient when performing calculations.

Now, , etc are Bessel functions. We can find numerical expressions for evaluating these in a text like Abramowitz and Stegun. Using these we can compute values. For the sake of clarity is is useful to plot values normalised in terms of . Some

materials with a high permittivity, large plate area and small distance between plates.

Theory of electrochemical construction

Besides the conventional static storage of electric energy in an electric field, two other storage principles to store electric energy in a capacitor exist. They are so-called electrochemical capacitors.in In contrast to ceramic, film and electrolytic capacitors, supercapacitors, also known as electrical double-layer capacitors (EDLC) or ultracapacitors do not have a conventional dielectric. The capacitance value of an electrochemical capacitor is determined by two high-capacity storage principles. These principles are:

* electrostatic storage within Helmholtz double layers achieved on the phase interface between the surface of the electrodes and the electrolyte (double-layer capacitance) and the

* electrochemical storage achieved by a faradaic electron charge-transfer by specifically adsorpted ions with redox reactions (pseudocapacitance)

Double-layer capacitance and pseudocapacitance combine to a form a supercapacitor.

Common capacitors and their names

Capacitors are divided into two mechanical groups: Fixed capacitors with fixed capacitance values and variable capacitors with variable (trimmer) or adjustable (tunable) capacitance values.

The most important group is the fixed capacitors. Many got their names from the dielectric. For a systematic classification these characteristics can't be used, because one of the oldest, the electrolytic capacitor, is named instead by its cathode construction. So the most-used names are simply historical.

The most common kinds of capacitors are:

* Ceramic capacitors have a ceramic dialectric.

* Film and paper capacitors are named for their dielectrics.

* Aluminum, tantalum and niobium electrolytic capacitors are named after the material used as the anode and the construction of the cathode

* Supercapacitor is the family name for:
  * Double-layer capacitors were named for the physical phenomenon of the Helmholtz double-layer
  * Pseudocapacitors were named for their ability to store electric energy electro-chemically with reversible faradaic charge-transfer
  * Hybrid capacitors combine double-layer and pseudocapacitors to increase power density

* Seldom-used Silver mica, glass, silicon, air-gap and vacuum capacitors were named for their dielectric.

Capacitors in each family have similar physical design features, but vary, for example, in the form of the terminals.

misunderstood, and hence people occasionally tend to invoke this frequency dependent behaviour as the implied basis for all kinds of claims regarding the ‘sounds’ of different types of cables. The purpose of this analysis is to throw some light into this area and help provide some understanding of the effects of using conductors of finite conductivity.

In engineering textbooks, the consequences of finite conductivity and wire size are treated in terms of an ‘Internal Impedance’. This term is probably more useful that ‘skin effect’ as it acts as a reminder that the effects arise due to the fields internal to the conductor. The internal impedance per unit length of a wire is considered in Ramo et al. From this was may draw the following results as a starting point.

The d.c. (i.e. very low frequency) impedance of a wire which has a circular cross-section and is uniform may be said to consist of a resistance per unit length of

$$R_0 = \frac{1}{\pi r_0^2 \sigma} \quad (1)$$

where is the bulk conductivity value appropriate for the material used to manufacture the wire, and is the radius of the wire. The resistance is in Ohms/metre if we are using S.I. units (which will be assumed from now on).

The wire will also exhibit an effective inductance per unit length at very low frequency due to its internal fields. At very low frequencies this has the value

$$L_0 = \frac{\mu}{8\pi} \quad (2)$$

where is the permeability of the material. In general we can assume that this equals the value for free space

$$\mu_0 = 4\pi \times 10^{-7} \quad \text{Henries/Metre}$$

Skin Effect, Internal Impedence, and types of wire

Jim Lesurf
University of St. Andrews, St Andrews, Fife KY16 9SS, Scotland
http://www.st-andrews.ac.uk/~www_pa/Scots_Guide/audio/skineffect/page1.html

1. Skin Effect and cable impedance

There is a considerable amount of discussion (not to say argument!) amongst those interested in audio and Hi-Fi about the possible effects of cables upon ‘sound quality’. This tends to lead to some people adopting almost ‘theological’ viewpoints that differ fundamentally from the views held by others. One of the technical factors which is sometimes claimed to affect sound quality is what is usually called ‘Skin effect’.

In most electronics textbooks, the properties of cables and wires are considered as a form of transmission line. The text may mention briefly the skin effect without exploring this in detail. More often, however, the only parameters that tend to be considered are the capacitance per length, inductance per length, and their relationship with the signal’s nominal propagation velocity and the characteristic impedance of the system. The fact that normal materials have a finite conductance (or resistance) is not usually considered beyond its effect upon the d.c. (and low frequency) resistance of the cables and the resulting implied signal power losses.

In reality, when we transmit alternating signals along conductive lines we may experience effects due to what is generally called ‘skin effects’. This subject is widely

---

In addition to the above shown capacitor types, which derived their name from historical development, there are many individual capacitors that have been named based on their application. They include:

* Power capacitors, motor capacitors, DC-link capacitors, suppression capacitors, audio crossover capacitors, lighting ballast capacitors, snubber capacitors, coupling, decoupling or bypassing capacitors.

Often, more than one capacitor family is employed for these applications, e.g. interference suppression can use ceramic capacitors or film capacitors.

Specialized devices such as built-in capacitors with metal conductive areas in different layers of a multi-layer printed circuit board and kludges such as twisting together two pieces of insulated wire also exist.

Dielectrics

The most common dielectrics are:

* Ceramics
* Plastic films
* Oxide layer on metal (Aluminum, Tantalum, Niobium)
* Natural materials like mica, glass, paper, air, vacuum

All of them store their electrical charge statically within an electric field between two (parallel) electrodes.

Beneath this conventional capacitors a family of electrochemical capacitors called Supercapacitors was developed. Supercapacitors don't have a conventional dielectric. They store their electrical charge statically in

* Helmholtz double-layers (Double-layer capacitors)

and additional electrochemical with faradaic charge transfer

* with a pseudocapacitance (Pseudocapacitors)
* or with both storage principles together (Hybrid capacitors).

The most important material parameters of the different dielectrics used and the appr. Helmholtz-layer thickness are given in the table below.

Table of Key parameters

I0(z) = Modified Bessel Function of First kind of order 0
I1(z) = Modified Bessel Function of First kind of order 1

The first mathematical discussions on the skin effect of wires were done by Maxwell, who started modern electromagnetics in 1873. This was followed by significant contributions by the creative genius Heaviside, who followed the theoretical work of Maxwell in 1884-1887, and by Poynting in 1884-1885. Experimental confirmation was first done by Hughes in 1886. Numerical engineering calculations on the applicable level was first done by Lord Rayleigh for the skin effect on infinite planes in 1886, and on cylindrical conductors by Lord Kelvin using ber-bei functions in 1899. Afterwards, there was work by Hertz and J.J. Thomson, who took over experimental work by Maxwell. The first person to use the word "skin effect" is considered to be J.Swinburne in 1891. Until recently, there were continuous challenges by many brilliant theorists and engineers, including H.B.Dwight and A.E.Kennelly.

For your information, the word "Litz wire" comes from the German word "Litzendraht" (twisted strands).

Kouichi Hirabayashi, (C) 2003

"if we increase the number of wires, we can make a cable with less skin effect. If company A has a product with 19 wires, we make one with 30 wires. If they beat us, we will increase the number of wires by one...".

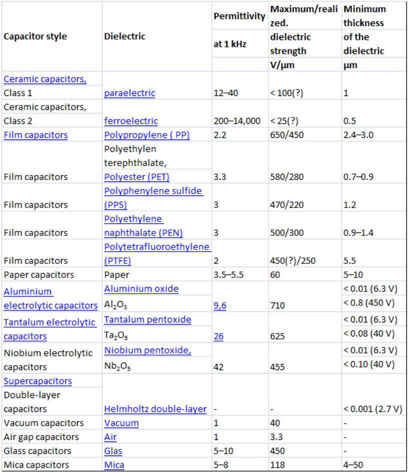
As a consequence, many audio cables with Litz wire were born. Is this strategy effective?

This is the question.

Footnote 1

Obtaining the current distribution of a single cylindrical conductor under high frequency is relatively simple, and the solution is shown below. The current distribution shown in Fig. 1 has been calculated using this equation. However, only the magnitude is shown. Note that the phase of the current also depends on the position. As we get deeper into the conductor from the surface, the phase of the current delays and may even become backward!

Ir / Ia = I0(sqrt(j)*k*r) / I0(sqrt(j)*k*a)
Here,
Ir = current density (A/m^2) at radius r (m)
Ia = current density at outer surface of conductor (A/m^2)
a = conductor radius (m)
j = sqrt(-1)
k = sqrt(w*u*g)
w = angular velocity (rad/s)
= 2*PI*f
PI = 3.14159265..
f = frequency (Hz)
u = permeability (H/m)
g = dielectric constant (S/m)



Capacitor style	Dielectric	Permittivity at 1 kHz	Maximum/realized. dielectric strength V/µm	Minimum thickness of the dielectric µm
Ceramic capacitors, Class 1	paraelectric	12–40	< 100(?)	1
Ceramic capacitors, Class 2	ferroelectric	200–14,000	< 25(?)	0.5

Glass capacitors	Glas	5–10	450	-
Mica capacitors	Mica	5–8	118	4–50

The capacitor's plate area can be adapted to the wanted capacitance value. The permittivity and the dielectric thickness are the determining parameter for capacitors. Ease of processing is also crucial. Thin, mechanically flexible sheets can be wrapped or stacked easily, yielding large designs with high capacitance values. Razor-thin metallized sintered ceramic layers covered with metallized electrodes however, offer the best conditions for the miniaturization of circuits with SMD styles.

A short view to the figures in the table above gives the explanation for some simple facts:

* Supercapacitors have the highest capacitance density because of its special charge storage principles
* Electrolytic capacitors have lesser capacitance density than supercapacitors but the the highest capacitance density of conventional capacitors because its thin dielectric.
* Ceramic capacitors class 2 have much higher capacitance values in a given case than class 1 capacitors because of their much higher permittivity.
* Film capacitors with their different plastic film material do have a small spread in the dimensions for a given capacitance/voltage value of a film capacitor because the minimum dielectric film thickness differs between the different film materials.

Ceramic capacitors

A ceramic capacitor is a non-polarized fixed capacitor made out of two or more alternating layers of ceramic and metal in which the ceramic material acts as the dielectric and the metal acts as the electrodes. The ceramic material is a mixture of finely ground granules of paraelectric or ferroelectric materials, modified by mixed oxides that are necessary to achieve the capacitor's desired characteristics. The electrical behavior of the ceramic material is divided into two stability classes:

The red, purple, green and light green lines correspond to the current density in the conductor cross-section for 10kHz, 100kHz, 1MHz and 10MHz respectively. The current density at the center of the conductor decreases from 98% of the surface for 10kHz, to 41% for 100kHz, to 0.4% for 1MHz, and to just 0.00000006 % for 10 MHz.

As a result of the skin effect, the effective cross-section of the conductor decreases and alternating current resistance increases. Therefore, in coil windings, conductor loss increases and the "Q" (quality factor), or quality, decreases with the increase in frequency.

As a countermeasure, from early times "Litz wire" was used for bar antenna coils in shortwave radios and mid-frequency transformer windings. Litz wire is many thin insulated conductor strands twisted together.

Many people considered applying the concept behind Litz wire to "audio cables", and came up with the idea as shown in Fig. 2.

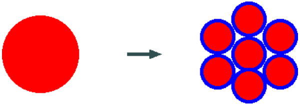

Fig. 2 Splitting a single wire conductor into many insulated conductors (conductors in red, insulators in blue)

Here, we split a single wire conductor into many insulated conductors with the same conductor cross-section area. For example, if we split into seven wires, we get the configuration shown in Fig. 2. People who think of these products think that

Skin effect and Litz wire

Kouichi Hirabayashi
http://www.mogami.com/e/puzzle/pzl-21.html

Current flowing through a cylindrical conductor distributes evenly along the conductor cross-section when the current is a direct current. However, with the increase in frequency, the effect where the current concentrates at the conductor surface and the current density decreases at the center, is known well as the skin effect (footnote 1).

For example, Fig. 1 shows the current density in the conductor cross-section of an annealed copper wire with a diameter of 1mm for frequencies 10kHz, 100kHz, 1MHz and 10MHz.

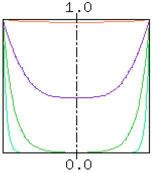

Fig. 1 Skin effect for annealed copper wire with a diameter of 1mm

The x-axis in Fig. 1 is the distance from the conductor center (center of the figure represents the center of the conductor and both ends show the conductor surface), and the y-axis is (internal current density/current density at conductor surface).

---

* Class 1 ceramic capacitors with high stability and low losses compensating the influence of temperature in resonant circuit application. Common EIA/IEC code abbreviations are C0G/NP0, P2G/N150, R2G/N220, U2J/N750 etc.

* Class 2 ceramic capacitors with high volumetric efficiency for buffer, by-pass and coupling applications Common EIA/IEC code abbreviations are: X7R/2XI, Z5U/E26, Y5V/2F4, X7S/2C1, etc.

The great plasticity of ceramic raw material works well for many special applications and enables an enormous diversity of styles, shapes and great dimensional spread of ceramic capacitors. The smallest discrete capacitor, for instance, is a "01005" chip capacitor with the dimension of only 0.4 mm × 0.2 mm.

The construction of ceramic multilayer capacitors with mostly alternating layers results in single capacitors connected in parallel. This configuration increases capacitance and decreases all losses and parasitic inductances. Ceramic capacitors are well-suited for high frequencies and high current pulse loads.

Because the thickness of the ceramic the dielectric layer can be easily controlled and produced by the desired application voltage, ceramic capacitors are available with rated voltages up to the 10 kV range.

Some ceramic capacitors of special shapes and styles are used as capacitors for special applications, including RFI/EMI suppression capacitors for connection to supply mains, also known as safety capacitors,[9][10] X2Y® capacitors for bypassing and decoupling applications,[11] feed-through capacitors for noise suppression by low-pass filters[12] and ceramic power capacitors for transmitters and HF applications.[13][14]

Film capacitors

Film capacitors or plastic film capacitors are non-polarized capacitors with an insulating plastic film as the dielectric. The dielectric films are drawn to a thin layer, provided with metallic electrodes and wound into a cylindrical winding. The electrodes of film capacitors may be metallized aluminum or zinc, applied on one or both sides of the plastic film, resulting in metallized film capacitors or a separate metallic foil overlying the film, called film/foil capacitors.

Metallized film capacitors offer self-healing properties. Dielectric breakdowns or shorts between the electrodes do not destroy the component. The metallized construction makes it possible to produce wound capacitors with larger capacitance values (up to 100 µF and larger) in smaller cases than within film/foil construction.

Film/foil capacitors or metal foil capacitors are use two plastic films as the dielectric. Each film is covered with a thin metal foil, mostly aluminium, to form the electrodes. The advantage of this construction is the ease of connecting the metal foil electrodes, along with an excellent current pulse strength.

A key advantage of every film capacitor's internal construction is direct contact to the electrodes on both ends of the winding. This contact keeps all current paths very short. The design behaves like a large number of individual capacitors connected in parallel, thus reducing the internal ohmic losses (ESR) and

simplicity facilitates finding those optimal diameters. Other models (such as [14] and the similar analysis in [17]) also model large strand diameters and circular bundle configurations accurately, but they fully calculate only internal, and not external, proximity effect, and so are not useful for the present purposes.

CONCLUSION

The number of strands for a minimum-loss litz-wire winding may be found by evaluating the tradeoff between proximity-effect losses and dc resistance. Of the factors leading to increased dc resistance in a litz-wire winding, only the space allocated to strand insulation varies significantly with the number of strands in a well designed construction. A power law can be used to model insulation thickness in the region of interest. Combining this with standard models for eddy-current loss results in an analytic solution for the optimal number of strands. The simplest model for loss, using only the first terms of a series expansion can be used since good designs use strands that are small compared to a skin depth. Experimental results correlate well with the simple model. Stranding for minimum loss may lead to many strands of fine wire and thus excessive expense. Minimum loss designs constrained by minimum strand size or maximum number of strands have also been derived.

where Fr is a factor relating dc resistance to an ac resistance which accounts for all winding losses, given a sinusoidal current with rms amplitude Iac. As shown in Appendix A, we can approximate Fr by

$$F_r = 1 + \frac{\pi^2 \omega^2 \mu_0^2 N^2 n^2 d_c^6 k}{768 \rho_c^2 b_c^2}$$

(2)

where ; is the radian frequency of a sinusoidal current, n is the number of strands, N is the number of turns, dc is the diameter of the copper in each strand, is the resistivity of the copper conductor, bc is the breadth of the window area of the core, and k is a factor accounting for field distribution in multi-winding transformers, normally equal to one (see Appendix A). For waveforms with a dc component, and for some non-sinusoidal waveforms, it is possible to derive a single equivalent frequency that may be used in this analysis (Appendix C). In an inductor, the field in the winding area depends on the gapping configuration, and this analysis is not directly applicable.

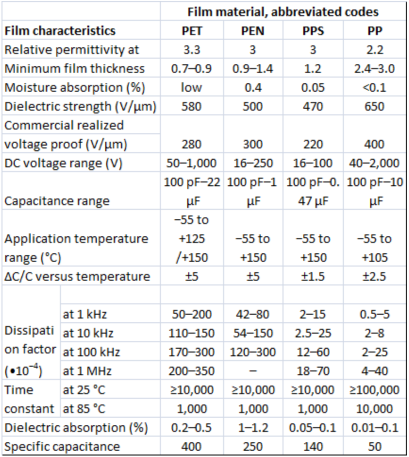
The analysis described here considers the strands of all litz bundles to be uniformly distributed in the window, as they would be in a single winding using N turns of wire the diameter of the litz strands. In fact, the strands are arranged in more or less circular bundles. In this sense, the analysis of [15] may be more accurate, but this difference has very little effect on the results. The most important difference between the model used here and the model in [15] is the greater accuracy of [15] for strands that are large compared to a skin depth. The simpler model is used because it is accurate for the small strand diameters that are found to be optimal, and because its

---

parasitic inductance (ESL). The inherent geometry of film capacitor structure results in low ohmic losses and a low parasitic inductance, which makes them suitable for applications with high surge currents (snubbers) and for AC power applications, or for applications at higher frequencies.

The plastic films used as the dielectric for film capacitors are Polypropylene (PP), Polyester (PET), Polyphenylene sulfide (PPS), Polyethylene naphthalate (PEN), and Polytetrafluoroethylene or Teflon (PTFE). Polypropylene film material with a market share of something about 50% and Polyester film with something about 40% are the most used film materials. The rest of something about 10% will be used by all other materials including PPS and paper with roughly 3%, each.[15][16]

Table Characteristics of plastic film materials for film capacitors



Film characteristics		PET	PEN	PPS	PP
		Film material, abbreviated codes			
Relative permittivity at		3.3	3	3	2.2
Minimum film thickness		0.7–0.9	0.9–1.4	1.2	2.4–3.0
Moisture absorption (%)		low	0.4	0.05	<0.1
Dielectric strength (V/µm)		580	500	470	650
Commercial realized voltage proof (V/µm)		280	300	220	400
DC voltage range (V)		50–1,000	16–250	16–100	40–2,000
Capacitance range		100 pF–22 µF	100 pF–1 µF	100 pF–0.47 µF	100 pF–10 µF
Application temperature range (°C)		−55 to +125 /+150	−55 to +150	−55 to +150	−55 to +105
ΔC/C versus temperature		±5	±5	±1.5	±2.5
Dissipation factor $(\bullet 10^{-4})$	at 1 kHz	50–200	42–80	2–15	0.5–5
	at 10 kHz	110–150	54–150	2.5–25	2–8
	at 100 kHz	170–300	120–300	12–60	2–25
	at 1 MHz	200–350	–	18–70	4–40
Time constant	at 25 °C	≥10,000	≥10,000	≥10,000	≥100,000
	at 85 °C	1,000	1,000	1,000	10,000
Dielectric absorption (%)		0.2–0.5	1–1.2	0.05–0.1	0.01–0.1
Specific capacitance		400	250	140	50

Some film capacitors of special shapes and styles are used as capacitors for special applications, including RFI/EMI suppression capacitors for connection to the supply mains, also known as safety capacitors,[17] Snubber capacitors for very high surge currents,[18] Motor run capacitors, AC capacitors for motor-run applications[19]

(the effect of current in other bundles) [14], [15]. However, the distinction is useful only as a form of bookkeeping. The actual losses in one strand of a litz bundle are simply a result of the total external field, due to the currents in all the other strands present. Another approach to calculating the loss in a litz winding is to look at it as a single winding, made up of nN turns of the strand wire, each with current i/n flowing in it, where n is the number of strands, N is the number of turns of litz wire, and i is current flowing in the overall litz bundle. The loss in the litz winding will be the same as in the equivalent single-strand winding as long as the currents flowing in all the strands are equal [16]. Other methods of calculating loss in litz wire also assume equal current in all strands [14], [12], [17]].

The objective of twisting or weaving litz wire, as opposed to just grouping fine conductors together, is to ensure that the strand currents are equal. Simple twisted bunched-conductor wire can accomplish this adequately in situations where proximity effect would be the only significant problem with solid wire. Where skin effect would also be a problem, more complex litz constructions can be used to ensure equal strand currents. Thus, in a well-designed construction, strand currents are very close to equal. However, our results remain valid even when simple twisting results in significant skin effect at the litz-bundle level. This is because the the bundle-level skin-effect loss is independent of the number of strands, and is orthogonal [15] to the strand-level eddy-current losses.

We represent winding losses by

$$P_{loss} = F_r I_{ac}^2 R_{dc}$$

(1)

All of these methods give similar results for strands that are small compared to the skin depth [12]. (See Appendix B for a discussion of one minor discrepancy.) The solutions for optimal stranding result in strand diameters much smaller than a skin depth. In this region the distinctions between the various methods evaporate, and the simplest analysis is adequate. More rigorous analysis (e.g. [12]) is important when strands are not small compared to a skin depth. In this case, losses are reduced relative to what is predicted by the analysis used here, due to the self-shielding effect of the conductor.

Previous work, such as [2] , [3], [4] has addressed optimal wire diameter for single-strand windings. The approach in [2], [3], [4] is also applicable for litz-wire windings in the case that the number of strands is fixed, and the strand diameter for lowest loss is desired. As discussed in Section V, this can be useful for cost-sensitive applications, if the number of strands is the determining factor in cost, and the maximum cost is constrained. However, this will, in general, lead to higher-loss designs than are possible using the optimal number of strands.

SKIN EFFECT, PROXIMITY EFFECT, AND LITZ WIRE

Skin effect is the tendency for high-frequency currents to flow on the surface of a conductor. Proximity effect is the tendency for current to flow in other undesirable patterns---loops or concentrated distributions---due to the presence of magnetic fields generated by nearby conductors. In transformers and inductors, proximity-effect losses typically dominate over skin-effect losses. In litz-wire windings, proximity effect may be further divided into internal proximity effect (the effect of other currents within the bundle) and external proximity effect

High pulse current load is the most important feature of film capacitors so many of the available styles do have special terminations for high currents

Electrolytic capacitors

Electrolytic capacitors have a metallic anode covered with an oxidized layer used as dielectric. The second electrode is a non-solid (wet) or solid electrolyte. Electrolytic capacitors are polarized. Three families are available, categorized according to their dielectric.

* Aluminum electrolytic capacitors with aluminum oxide as dielectric
* Tantalum electrolytic capacitors with tantalum pentoxide as dielectric
* Niobium electrolytic capacitors with niobium pentoxide as dielectric.

The anode is highly roughened to increase the surface area. This and the relatively high permittivity of the oxide layer gives these capacitors very high capacitance per unit volume compared with film- or ceramic capacitors.

The permittivity of tantalum pentoxide is approximately three times higher than aluminium dioxide, producing significantly smaller components. However, permittivity determines only the dimensions. Electrical parameters, especially conductivity, are established by the electrolyte's material and composition. Three general types of electrolytes are used:

* non solid (wet, liquid)—conductivity approximately 10 mS/cm and are the lowest cost

* solid manganese oxide—conductivity approximately 100 mS/cm offer high quality and stability
* solid conductive polymer (Polypyrrole)—conductivity approximately 10,000 mS/cm,[21] offer ESR values as low as <10 mΩ

Internal losses of electrolytic capacitors, prevailing used for decoupling and buffering applications, are determined by the kind of electrolyte.

Table Some important values of the different electrolytic capacitors

loss. This paper presents a method of finding that optimum, using standard methods of estimating the eddy-current losses.
Optimizations on magnetics design may be done to minimize volume, loss, cost, weight, temperature rise, or some combination of these factors. For example, in the design of magnetic components for a solar-powered race vehicle [1] (the original impetus for this work) an optimal compromise between loss and weight is important. Although we will explicitly minimize only winding loss, the results are compatible with and useful for any minimization of total loss (including core loss), temperature rise, volume or weight. This is because the only design change considered is a change in the degree of stranding, preserving the overall diameter per turn and overall window area usage. This does not affect core loss or volume, and has only a negligible effect on weight. However, the degree of stranding does significantly affect cost. Although we have not attempted to quantify or optimize this, additional results presented in Section V are useful for cost-constrained designs. The analysis of eddy-current losses used here does not differ substantially from previous work [2], [3], [4], [5], [6], [7], [8], [9], [10], [11], [12], [13] ([10] gives a useful review). Although different descriptions can be used, most calculations are fundamentally equivalent to one of three analyses. The most rigorous approach uses an exact calculation of losses in a cylindrical conductor with a known current, subjected to a uniform external field, combined with an expression for the field as a function of one-dimensional position in the winding area [12]. Perhaps the most commonly cited analysis [11] uses "equivalent" rectangular conductors to approximate round wires, and then proceeds with an exact one-dimensional solution. Finally, one may use only the first terms of a series expansion of these solutions, e.g. [9].

Skin Effect, Proximity Effect, and Litz Wire

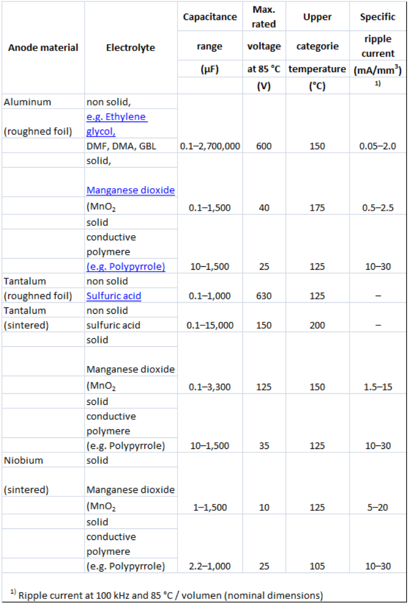
Charles R. Sullivan
Thayer School of Engineering, Dartmouth College
http://www.dartmouth.edu/~sullivan/litzwire/litz.html

INTRODUCTION

A salient difficulty in designing high-frequency inductors and transformers is eddy-current effects in windings. These effects include skin-effect losses and proximity-effect losses. Both effects can be controlled by the use of conductors made up of multiple, individually insulated strands, twisted or woven together. Sometimes the term litz wire is reserved for conductors constructed according to a carefully prescribed pattern, and strands simply twisted together are called bunched wire. We will use the term litz wire for any insulated grouped strands, but will discuss the effect of different constructions.

This paper addresses the choice of the degree of stranding in litz wire for a transformer winding. The number of turns and the winding cross-sectional area are assumed to be fixed. The maximum cross-sectional area of each turn is thus fixed, and as the number of strands is increased, the cross-sectional area of each strand must be decreased. This typically leads to a reduction in eddy-current losses. However, as the number of strands increases, the fraction of the window area that is filled with copper decreases and the fraction filled with insulation increases.This results in an increase in dc resistance. Eventually, the eddy-current losses are made small enough that the increasing dc resistance offsets any further improvements in eddy-current loss, and the losses start to increase. Thus, there is an optimal number of strands that results in minimum

---



Anode material	Electrolyte	Capacitance range (µF)	Max. rated voltage at 85 °C (V)	Upper categorie temperature (°C)	Specific ripple current (mA/mm^3) 1)

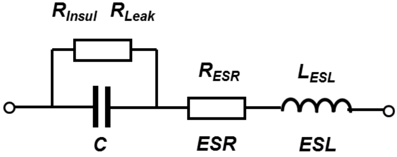
1) Ripple current at 100 kHz and 85 °C / volumen (nominal dimensions)

The large capacitance per unit volume of electrolytic capacitors make them valuable in relatively high-current and low-frequency electrical circuits, e.g. in power supply filters for decoupling unwanted AC components from DC power connections or as coupling capacitors in audio amplifiers, for passing or bypassing low-frequency signals and storing large amounts of energy. The relatively high capacitance value of an electrolytic capacitor combined with the very low ESR of the polymer electrolyte of polymer capacitors, especially in SMD styles, makes them a competitor to MLC chip capacitors in personal computer power supplies.

Bipolar electrolytics (also called Non-Polarized capacitors) contain two anodized aluminium foils, behaving like two capacitors connected in series opposition.

Electolytic capacitors for special applications include motor start capacitors,[22] flashlight capacitors[23] and audio frequency capacitors.[24]

Electrical characteristics



Series-equivalent circuit

Do = Diameter of the finished cable over the strands in inches = 0.056
K = Constant depending on the number of strands = 2

Rac/Rdc = 1.0003 +2(660*0.0016 / 0.056)^2 * (0.0016*1000 / 10.44)^4 = 1.393

Therefore the AC Resistance of 660/46 litz wire is: 1.39 * 7.27 = 10.13 ohms/1000ft.

A 5inch diameter basket weave coil made from 660/46 Litz wire having an inductance of 230 uH will typically require some 40 turns or about 53ft of wire. At 10.13 Ohm/kft, that comes to an AC wire resistance of 0.53 ohms for the coil alone. Were all the losses represented by just the wire, the coil would have, at 1 MHz an unloaded Q = 2700!

Naturally, wire resistance is not the only source of loss in the tank. There is a capacitor, metallic objects intruding into the magnetic field of the coil, diaelectric losses, eddy current and other losses. Its no wonder that the best coils just top out above Q = 1000 or so.

kjs

Litz Coil wire Resistance Calculation

Kevin Smith

From different Litz wire manufacturing sites one can find tables and data allowing the calculation of the resistance of your favorite litz wire.

The formula for the D.C. resistance of any Litz construction is:

Rdc = Rs (1.0515)^Nb * (1.025)^Nc / Ns

Where:
Rdc = Resistance in Ohms/1000 ft.
Rs = Maximum D.C. resistance of the individual strands (4544 for 46awg wire)
Nb = Number of Bunching operations (assume = 2)
Nc = Number of Cabling operations (assume = 1)
Ns = Number of individual strands (assume = 660)

Rdc = 4544 (1.015)^2 (1.025)^1 / 660 = 7.27 ohms / 1000 ft.

The ratio of AC resistance to DC resistance of any Litz construction is:

Rac/Rdc = S + K (N Di / Do)^2 * G

Where:
S = Resistance ratio of individual strands when isolated (1.0003 for 46awg wire)
G = Eddy Current basis factor = (Di * sqrt(f) / 10.44)^4
F = Operating Frequency in HZ (assume 1MHz)
N = Number of strands in the cable = 660
Di = Diameter of the individual strands over the copper in inches = 0.0016

Discrete capacitors deviate from the ideal capacitor. An ideal capacitor only stores and releases electrical energy, with no dissipation. Capacitor components have losses and parasitic inductive parts. These imperfections in material and construction can have positive implications such as linear frequency and temperature behavior in class 1 ceramic capacitors. Conversely, negative implications include the non-linear, voltage-dependent capacitance in class 2 ceramic capacitors or the insufficient dielectric insulation of capacitors leading to leakage currents.

All properties can be defined and specified by a series equivalent circuit composed out of an idealized capacitance and additional electrical components which model all losses and inductive parameters of a capacitor. In this series-equivalent circuit the electrical characteristics are defined by:

* C, the capacitance of the capacitor
* Rinsul, the insulation resistance of the dielectric, not to be confused with the insulation of the housing
* Rleak, the resistance representing the leakage current of the capacitor
* RESR, the equivalent series resistance which summarizes all ohmic losses of the capacitor, usually abbreviated as "ESR"
* LESL, the equivalent series inductance which is the effective self-inductance of the capacitor, usually abbreviated as "ESL".

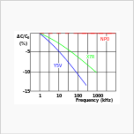
Using a series equivalent circuit instead of a parallel equivalent circuit is specified by IEC/EN 60384-1.

Frequency dependence

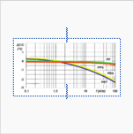
Most discrete capacitor types have more or less capacitance changes with increasing frequencies. The dielectric strength of class 2 ceramic and plastic film diminishes with rising frequency. Therefore their capacitance value decreases with increasing frequency. This phenomenon for ceramic class 2 and plastic film dielectrics is related to dielectric relaxation in which the time constant of the electrical dipoles is the reason for the frequency dependence of permittivity. The graphs below show typical frequency behavior of the capacitance for ceramic and film capacitors.

For electrolytic capacitors with non-solid electrolyte, mechanical motion of the ions occurs. Their movability is limited so that at higher frequencies not all areas of the roughened anode structure are covered with charge-carrying ions. As higher the anode structure is roughned as more the capacitance value decreases with increasing frequency. Low voltage types with highly-roughened anodes display capacitance at 100 kHz approximately 10 to 20% of the value measured at 100 Hz.

Frequency dependence of capacitance for ceramic and film capacitors



Frequency dependence of capacitance for ceramic class 2 capacitors (NP0 class 1 for comparisation)



Frequency dependence of capacitance for film capacitors with different film materials

Wire-Gauge Ampacity

http://wiki.xtronics.com/index.php/Wire-Gauge_Ampacity

Material	Melt pt °C	Resistivity (Ω-m) at 20 °C
Silver	961.78	1.59×10-8
Copper	1084.62	1.72×10-8
Aluminum	660.32	2.82×10-8
Iron	1538	1.0×10-7
Tin	231.93	1.09×10-7
Platinum	1768.3	1.1×10-7
Lead	327.46	2.2×10-7
Tin/lead solder	183	1.44x10-7

Resistivities at room temp:

http://www.epanorama.net/documents/wiring/wire_resistance.html

Element	Electrical resistivity (microohm-cm)
Aluminum	2.655
Copper	1.678
Gold	2.24
Silver	1.586
Platinum	10.5

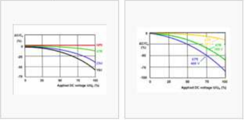
This clearly puts silver as the number one conductor and gold has higher resistance than silver or copper. It's desireable in connectors because it does not combine well with other materials so remains relatively pure at the surface. It also has the capability to adhere to itself (touch pure gold to pure gold and it sticks together) which makes for very reliable connections.

Voltage dependence

Capacitance may also change with applied voltage. This effect is more prevalent in class 2 ceramic capacitors. The permittivity of ferroelectric class 2 material depends on the applied voltage. Higher applied voltage lowers permittivity. The change of capacitance can drop to 80% of the value measured with the standardized measuring voltage of 0.5 or 1.0 V. This behavior is a small source of non-linearity in low-distortion filters and other analog applications. In audio applications this can be the reason for harmonic distortion.

Film capacitors and electrolytic capacitors have no significant voltage dependence.

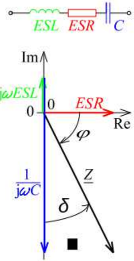
Voltage dependence of capacitance for some different class 2 ceramic capacitors



Simplified diagram of the change in capacitance as a function of the applied voltage for 25-V capacitors in different kind of ceramic grades

Simplified diagram of the change in capacitance as a function of applied voltage for X7R ceramics with different rated voltages

Impedance



Simplified series-equivalent circuit of a capacitor for higher frequencies (above); vector diagram with electrical reactances XESL and XC and resistance ESR and for illustration the impedance Z and dissipation factor tan δ

In general, a capacitor is seen as a storage component for electric energy. But this is only one capacitor function. A capacitor can also act as an AC resistor. In many cases the capacitor is used as a decoupling capacitor to filter or bypass undesired biased AC frequencies to the ground. Other applications use capacitors for capacitive coupling of AC signals; the dielectric is used only for blocking DC. For such applications the AC resistance is as important as the capacitance value.

The frequency dependent AC resistance is called impedance \scriptstyle Z and is the complex ratio of the voltage to the current in an AC circuit. Impedance extends the concept of resistance to AC circuits and possesses both magnitude and phase at a particular frequency. This is unlike resistance, which has only magnitude.

$$Z = |Z|e^{j\theta}$$

The magnitude \scriptstyle |Z| represents the ratio of the voltage difference amplitude to the current amplitude,

\scriptstyle j is the imaginary unit, while the argument \scriptstyle \theta gives the phase difference between voltage and current.

In capacitor data sheets, only the impedance magnitude |Z| is specified, and simply written as "Z" so that the formula for the impedance can be written in Cartesian form

$$Z = R + jX$$

where the real part of impedance is the resistance \scriptstyle R (for capacitors \scriptstyle ESR) and the imaginary part is the reactance \scriptstyle X.

As shown in a capacitor's series-equivalent circuit, the real component includes an ideal capacitor C, an inductance L (ESL) and a resistor R (ESR). The total reactance at the angular frequency ω therefore is given by the geometric (complex) addition of a capacitive reactance (Capacitance) $X_C = -\frac{1}{\omega C}$ and an inductive reactance $X_L = \omega L_{\mathrm{ESL}}$.

To calculate the impedance \scriptstyle Z the resistance has to be added geometrically and then Z is given by

$$Z = \sqrt{ESR^2 + (X_\mathrm{C} + (-X_\mathrm{L}))^2}.$$

The impedance is a measure of the capacitor's ability to pass alternating currents. In this sense the impedance can be used like Ohms law

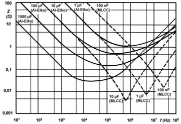
$$Z = \frac{\hat{u}}{\hat{\imath}} = \frac{U_\mathrm{eff}}{I_\mathrm{eff}}.$$

to calculate either the peak or the effective value of the current or the voltage.

In the special case of resonance, in which the both reactive resistances

$$X_C = -\frac{1}{\omega C} \text{ and } X_L = \omega L_{\mathrm{ESL}}$$

have the same value $(X_C = X_L)$ then the impedance will only be determined by {ESR}.



Typical impedance curves for different capacitance values over frequency showing the typical form with a decreasing impedance values below resonance and increasing values above resonance. As higher the capacitance as lower the resonance.

The impedance specified in the datasheets often show typical curves for the different capacitance values. With increasing frequency as the impedance decreases down to a minimum. The lower the impedance, the more easily alternating currents can be passed through the capacitor. At the apex, the point of resonance, where XC has the same value than XL, the capacitor has the lowest impedance value. Here only the ESR determines the impedance. With frequencies above the resonance the impedance increases again due to the ESL of the capacitor. The capacitor becomes to an inductance.

As shown in the graph the higher capacitance values can fit the lower frequencies better while the lower capacitance values can fit better the higher frequencies.

Aluminum electrolytic capacitors have relatively good decoupling properties in the lower frequency range up to about 1 MHz due to their large capacitance values. This is the reason for using electrolytic capacitors in standard or switched-mode power supplies behind the rectifier for smoothing application.

Ceramic and film capacitors are already out of their smaller capacitance values suitable for higher frequencies up to several 100 MHz. They also have significantly lower parasitic inductance, making them suitable for higher frequency applications, due to their construction with end-surface contacting of the electrodes. To increase the range of frequencies, often an electrolytic capacitor is connected in parallel with a ceramic or film capacitor.[36]

Many new developments are targeted at reducing parasitic inductance (ESL). This increases the resonance frequency of the capacitor and, for example, can follow the constantly increasing switching speed of digital circuits. Miniaturization, especially in the SMD multilayer ceramic chip capacitors (MLCC), increases the resonance frequency. Parasitic inductance is further lowered by placing the electrodes on the longitudinal side of the chip instead of the lateral side. The "face-down" construction associated with multi-anode technology in tantalum electrolytic capacitors further reduced ESL. Capacitor families such as the so-called MOS capacitor or silicon capacitors offer solutions when capacitors at frequencies up to the GHz range are needed.

Inductance (ESL) and self-resonant frequency

ESL in industrial capacitors is mainly caused by the leads and internal connections used to connect the capacitor plates to the outside world. Large capacitors tend to have higher ESL than small ones because the distances to the plate are longer and every mm counts as an inductance.

For any discrete capacitor, there is a frequency above DC at which it ceases to behave as a pure capacitor. This frequency, where XC is as high as XL, is called the self-resonant frequency. The self-resonant frequency is the lowest frequency at which the impedance passes through a minimum. For any AC application the self-resonant frequency is the highest frequency at which capacitors can be used as a capacitive component.

This is critically important for decoupling high-speed logic circuits from the power supply. The decoupling capacitor supplies transient current to the chip. Without decouplers, the IC demands current faster than the connection to the power supply can supply it, as parts of the circuit rapidly switch on and off. To counter this potential problem, circuits frequently use multiple bypass capacitors—small (100 nF or less) capacitors rated for high frequencies, a large electrolytic capacitor rated for lower frequencies and occasionally, an intermediate value capacitor.

Q factor

The quality factor (or Q) of a capacitor is the ratio of its reactance to its resistance at a given frequency, and is a measure of its efficiency. The higher the Q factor of the capacitor, the closer it approaches the behavior of an ideal, lossless, capacitor.

---

1. Calculate the D.C. resistance of the Litz construction using Formula 3.
Rdc = 681.90 (1.015)^2 (1.025)^1 / 400 = 1.80 ohms / 1000 ft.

2. Calculate the A.C. to D.C. Resistance Ratio using Formula 2.

$$\frac{R_{AC}}{R_{DC}} = 1.000 + 2\left(\frac{400 \times 0.0045}{0.1040}\right)^2 \times \left(\frac{0.0045 \quad 50000}{10.44}\right)^4 = 1.2068$$

3. The A.C. resistance is, therefore, 1.2068 x or 1.80 ohms/1000ft.

*****

Following is an example of the calculations required to evaluate a Type 2 Litz construction consisting of 650 strands of 46 AWG single-film polyurethane-coated wire operating at 1.0 MHZ.

1. Calculate the D.C. resistance of the Litz construction using Formula 3.
Rdc = 4544 (1.015)^2 (1.025)^1 / 660 = 7.27 ohms / 1000 ft.

2. Calculate the A.C. to D.C. Resistance Ratio using Formula 2.

Rac/Rdc = 1.0003 +2(660*0.0016 / 0.056)^2 *
(0.0016*1000 / 10.44)^4 = 1.393

3. The A.C. resistance is, therefore, 1.39*7.27 = **10.13** ohms/1000ft.

The D.C. Resistance of a Litz conductor is related to the following parameters:

1. Individual strands AWG.
2. Number of strands in the cable.
3. Factors relating to the increased length of the individual strands per unit length of cable (take - up). For standard Litz constructions a 1.5% increase in D.C. resistance for every bunching operation and a 2.5% increase in D.C. resistance for every cabling operation are roughly correct.

The formula derived from these parameters for the D.C. resistance of any Litz construction is:

$$R_{DC} = \frac{R_S\,(1.015)^{N_B}\,(1.025)^{N_C}}{N_S}$$

Where: Rdc = Resistance in Ohms/1000 ft.
Rs = Maximum D.C. resistance of the individual strands (taken from Table 2).
Nb = Number of Bunching operations
Nc = Number of Cabling operations
Ns = Number of individual strands

Following is an example of the calculations required to evaluate a Type 2 Litz construction consisting of 400 strands of 38 AWG single-film polyurethane-coated wire operating at 500 KHZ. This construction, designed with two bunching operations and one cabling operation, would be written 5 x 5 / 16 / 40 AWG (HM Wire uses x to indicate a cabling operation and / to indicate a bunching operation.)

The Q factor of a capacitor can be found through the following formula:

$$Q = \frac{X_C}{R_C} = \frac{1}{\omega C R_C}$$

Where:

ω is frequency in radians per second,
C is the capacitance,
X_C is the capacitive reactance, and
R_C is the series resistance of the capacitor.

Ohmic losses, ESR, dissipation factor, and quality factor

The summarized losses in discrete capacitors are ohmic AC losses. DC losses are specified as "leakage current" or "insulating resistance" and are negligible for an AC specification. AC losses are non-linear, possibly depending on frequency, temperature, age or humidity. The losses result from two physical conditions:

* line losses including internal supply line resistances, the contact resistance of the electrode contact, line resistance of the electrodes, and in "wet" aluminum electrolytic capacitors and especially supercapacitors, the limited conductivity of liquid electrolytes and
* dielectric losses from dielectric polarization.

The largest share of these losses in larger capacitors is usually the frequency dependent ohmic dielectric losses. For smaller components, especially for wet electrolytic capacitors, conductivity of liquid electrolytes may exceed dielectric losses. To measure these losses, the measurement frequency must be set. Since commercially available components offer capacitance values cover 15 orders of magnitude, ranging from pF (10–12 F) to some 1000 F in supercapacitors, it is not possible to capture the entire range with only one frequency. IEC 60384-1 states that ohmic losses should be measured at the same frequency used to measure capacitance. These are:

* 100 kHz, 1 MHz (preferred) or 10 MHz for non-electrolytic capacitors with CR ≤ 1 nF:
* 1 kHz or 10 kHz for non-electrolytic capacitors with 1 nF < CR ≤ 10 μF
* 100/120 Hz for electrolytic capacitors
* 50/60 Hz or 100/120 Hz for non-electrolytic capacitors with CR > 10 μF

A capacitor's summarized resistive losses may be specified either as ESR, as a dissipation factor(DF, tan δ), or as quality factor (Q), depending on application requirements.

Capacitors with higher ripple current I_R loads, such as electrolytic capacitors, are specified with equivalent series resistance ESR. ESR can be shown as an ohmic part in the above vector diagram. ESR values are specified in datasheets per individual type.

The losses of film capacitors and some class 2 ceramic capacitors are mostly specified with the dissipation factor tan δ. These capacitors have smaller losses than electrolytic capacitors and mostly are used at higher frequencies up to some hundred MHz. However the numeric value of the dissipation factor, measured at the same frequency, is independent on the capacitance value and can be specified for a capacitor series with a range of capacitance. The dissipation

---

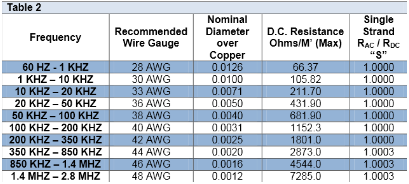

Table 2

Frequency	Recommended Wire Gauge	Nominal Diameter over Copper	D.C. Resistance Ohms/M' (Max)	Single Strand R_{AC} / R_{DC} "S"
60 HZ - 1 KHZ	28 AWG	0.0126	66.37	1.0000
1 KHZ – 10 KHZ	30 AWG	0.0100	105.82	1.0000
10 KHZ – 20 KHZ	33 AWG	0.0071	211.70	1.0000
20 KHZ – 50 KHZ	36 AWG	0.0050	431.90	1.0000
50 KHZ – 100 KHZ	38 AWG	0.0040	681.90	1.0000
100 KHZ – 200 KHZ	40 AWG	0.0031	1152.3	1.0000
200 KHZ – 350 KHZ	42 AWG	0.0025	1801.0	1.0000
350 KHZ – 850 KHZ	44 AWG	0.0020	2873.0	1.0003
850 KHZ – 1.4 MHZ	46 AWG	0.0016	4544.0	1.0003
1.4 MHZ – 2.8 MHZ	48 AWG	0.0012	7285.0	1.0003

After the individual wire gauge has been decided and assuming that the Litz construction has been designed such that each strand tends to inhabit all possible positions in the cable to just about the same extent, the ratio of A.C to D/C resistance of an remote Litz conductor can be determined from the following formula.

$$\frac{\textbf{Resistance to Alternating Current}}{\textbf{Resistance to Direct Current}} = S + K\left(\frac{N D_I}{D_O}\right)^2 G$$

Where:
S =Resistance ratio of individual strands when isolated (taken from Table 1 or 2)

G =Eddy Current basis factor = $\left(\frac{D_I\sqrt{F}}{10.44}\right)^4$
F =Operating Frequency in HZ
N =Number of strands in the cable
Dl =Diameter of the individual strands over the copper in inches
Do =Diameter of the finished cable over the strands in inches
K =Constant depending on N, given in the following table:

N	3	9	27	Infinity
K	1.55	1.84	1.92	2

Litz Designing Calculations
HM Wire International, Inc.
http://www.litz-wire.com/New%20PDFs/Litz_Designing_Calculations.pdf

Typically, the designing engineer that uses Litz knows the operating frequency and RMS current required for his application. Since the main advantage of a Litz conductor is the reduction of AC losses, the first thought in any Litz design is the operating frequency. The operating frequency not only influences the authentic Litz construction, it also determines the individual wire gauge.

Ratios of alternating-current resistance to direct-current resistance for an isolated solid round wire (S) in terms of a value (X) are shown in Table 1.

Table 1

X	0	0.5	0.6	0.7	0.8	0.9	1.0
S	1.0000	1.0003	1.0007	1.0012	1.0021	1.0034	1.005

The Value of X for copper wire is determined by Formula 1.

$$X=0.271\ D_M\sqrt{F_{MHZ}}$$

Where: Dm = Wire Diameter in mils
Fmhz = Frequency in Megahertz

From Table 1 and other practical data, the following table of recommended wire gauges vs. frequency for most Litz constructions has been prepared.

Table 2

---

factor is determined as the tangent of the reactance (X_C - X_L) and the ESR, and can be shown as the angle δ between imaginary and the impedance axis.

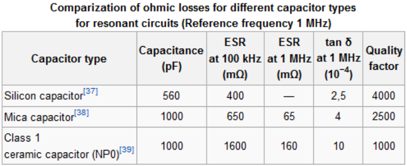
If the inductance ESL is small, the dissipation factor can be approximated as:

$$\tan\delta = ESR\cdot\omega C$$

Capacitors with very low losses, such as ceramic Class 1 and Class 2 capacitors, specify resistive losses with a quality factor (Q). Ceramic Class 1 capacitors are especially suitable for LC resonant circuits with frequencies up to the GHz range, and precise high and low pass filters. For an electrically resonant system, Q represents the effect of electrical resistance and characterizes a resonator's bandwidth B relative to its center or resonant frequency f_0. Q is defined as the reciprocal value of the dissipation factor.

$$Q = \frac{1}{tan\delta} = \frac{f_0}{B}$$

A high Q value is for resonant circuits a mark of the quality of the resonance.



Comparization of ohmic losses for different capacitor types for resonant circuits (Reference frequency 1 MHz)

Capacitor type	Capacitance (pF)	ESR at 100 kHz (mΩ)	ESR at 1 MHz (mΩ)	tan δ at 1 MHz (10^{-4})	Quality factor
Silicon capacitor[37]	560	400	—	2,5	4000
Mica capacitor[38]	1000	650	65	4	2500
Class 1 ceramic capacitor (NP0)[39]	1000	1600	160	10	1000

Equivalent series resistance

In a non-electrolytic capacitor and electrolytic capacitors with solid electrolyte the metallic resistance of the leads and electrodes and losses in the dielectric cause the ESR. Typically quoted values of ESR for ceramic capacitors are between 0.01 and 0.1 ohms. ESR of non-electrolytic capacitors tends to be fairly stable over time; for most purposes real non-electrolytic capacitors can be treated as ideal components.

Aluminium and tantalum electrolytic capacitors with non solid electrolyte have much higher ESR values, up to several ohms, and ESR tends to increase with frequency due to effects of the electrolyte. A very serious problem, particularly with aluminium electrolytics, is that ESR increases over time with use; ESR can increase enough to cause circuit malfunction and even component damage,[1] although measured capacitance may remain within tolerance. While this happens with normal aging, high temperatures and large ripple current exacerbate the problem. In a circuit with significant ripple current, an increase in ESR will increase heat dissipation, thus accelerating aging.

Electrolytic capacitors rated for high-temperature operation and of higher quality than basic consumer-grade parts are less susceptible to become prematurely unusable due to ESR increase. A cheap electrolytic capacitor may be rated for a life of less than 1000 hours at 85°C (a year is about 9000 hours). Higher-grade parts are typically rated at a few thousand hours at maximum rated temperature, as can be seen from manufacturers' datasheets. Electrolytics of higher capacitance have lower ESR; if ESR is critical, specification of a part of larger capacitance than is otherwise required may be advantageous.

http://www.eece.ksu.edu/~gjohnson/tcchap3.pdf

Polymer capacitors usually have lower ESR than wet-electrolytic of same value, and stable under varying temperature. Therefore polymer capacitors can handle higher ripple current. From about 2007 it became common for better-quality computer motherboards to use only polymer capacitors where wet electrolytics had been used previously.[2]

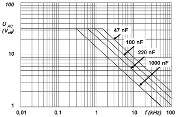
The ESR of capacitors of relatively high capacity (from about 1 µF), which are the ones likely to cause trouble, is easily measured in-circuit with an ESR meter.

Typical values of ESR for capacitors

Type	22 µF	100 µF
Standard aluminum	0.1 - 3.0 Ω	0.05 - 0.5 Ω
Ceramic	<0.015 Ω	

AC current

An AC load only can be applied to a non-polarized capacitor. Capacitors for AC applications are primarily film capacitors, metallized paper capacitors, ceramic capacitors and bipolar electrolytic capacitors.



The rated AC load for an AC capacitor is the maximum sinusoidal effective AC current (rms) which may be applied continuously to a capacitor within the specified temperature range. In the datasheets the AC load may be expressed as

* rated AC voltage at low frequencies,
* rated reactive power at intermediate frequencies,
* reduced AC voltage or rated AC current at high frequencies.

Typical rms AC voltage curves as a function of frequency, for 4 different capacitance values of a 63 V DC film capacitor series

The rated AC voltage for film capacitors is generally calculated so that an internal temperature rise of 8 to 10 °K is the allowed limit for safe operation. Because dielectric losses increase with increasing frequency, the specified AC voltage has to be derated at higher frequencies. Datasheets for film capacitors specify special curves for derating AC voltages at higher frequencies.

If film capacitors or ceramic capacitors only have a DC specification, the peak value of the AC voltage applied has to be lower than the specified DC voltage.

AC loads can occur in AC Motor run capacitors, for voltage doubling, in snubbers, lighting ballast and for power factor correction PFC for phase shifting to improve transmission network stability and efficiency, which is one of the most important applications for large power capacitors. These mostly large PP film or metallized paper capacitors are limited by the rated reactive power VAr.

Bipolar electrolytic capacitors, to which an AC voltage may be applicable, are specified with a rated ripple current.

Insulation resistance and self-discharge constant

The resistance of the dielectric is finite, leading to some level of DC "leakage current" that causes a charged capacitor to lose charge over time. For ceramic and film capacitors, this

134	1025	0.0006250	1600	0.852
48	1712	0.0019341	517	6.425

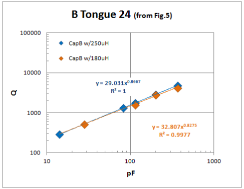
On the main plot then I have included for Ben's Cap B a second Q vs. ESR curve to illustrate the estimated benefit of using a higher tuning capacitance range. The new curve slides mostly to lower ESR (especially at the high end of the tuning range) and also to slightly lower Q. The improvements made appear modest from the modeled data and, for the case of a high-Q capacitor the possible improvements may be slight indeed. It is comforting to know that at least there should be no negative impact. Lower ESR certainly improves tank overall efficiency. This is a win-win situation where the set designer wins twice!

In seeking the "Holy Grail" tank capacitor I would add to the list of valuable features. We have ceramic stator supports, silver plating on the vanes, and good wiper contacts as features desired. I would add to this an extended tuning range if the capacitor is truly to be considered "Holy". With a standard 230 uH coil the tuning for the BCB ranges from 40 to 380 pF or so. With a 180 uH coil the capacitance needed ranges from 50 to 490 pF, (stray capacitance not accounted for).

Two questions immediately come to mind with this analysis:

1) To how low a coil inductance can you go?
2) If you find a few of these super-caps can you send me one?

kjs 6/2013 (in France)



provides the estimated Q, and calculated D, and ESR for the capacitances from Fig 5 (with 20pF stray added). The values of Q do not improve by moving to higher capacitances but the ESR of the cap is slightly (at low tuning freq) and well improved (at the high tuning freq). This is the goal. It is worthy to note that the tuning frequencies do not line up with the original data from Ben's Fig 3 as seen on my main plot. While Ben specifically noted that his figure 3 included 20pF strays, in his figure 5 he speaks in absolute capacitances. I did my best to correct for this but there remains some ambiguity in the presentation. The point remains though; moving to higher capacitances in the tank will lower the tank losses due to ESR.

250 inductor (w/20pF stray)

tank pF	KHz	D	Q	ESR ohm
385	513	0.0002083	4800	0.177
220	679	0.0003448	2900	0.404
134	870	0.0005714	1750	0.917
101	1000	0.0007638	1309	1.502
34	1726	0.0034973	286	23.046

180 inductor (w/20pF stray)

tank pF	KHz	D	Q	ESR ohm

220	800	0.0003571	2800	0.355

---

resistance is called "insulation resistance Rins". This resistance is represented by the resistor Rins in parallel with the capacitor in the series-equivalent circuit of capacitors. Insulation resistance must not be confused with the outer isolation of the component with respect to the environment.

The time curve of self-discharge over insulation resistance with decreasing capacitor voltage follows the formula

$$u(t) = U_0 \cdot \mathrm{e}^{-t/\tau_\mathrm{s}},$$

With stored DC voltage U_0 and self-discharge constant

$$\tau_\mathrm{s} = R_\mathrm{ins} \cdot C$$

Thus, after τ_s voltage U_0 drops to 37 % of the initial value.

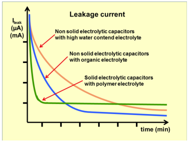
The self-discharge constant is an important parameter for the insulation of the dielectric between the electrodes of ceramic and film capacitors. For example, a capacitor can be used as the time-determining component for time relays or for storing a voltage value as in a sample and hold circuits or operational amplifiers.

Class 1 ceramic capacitors have an insulation resistance of at least 10 GΩ, while class 2 capacitors have at least 4 GΩ or a self-discharge constant of at least 100 s. Plastic film capacitors typically have an insulation resistance of 6 to 12 GΩ. This corresponds to capacitors in the uF range of a self-discarge constant of about 2000–4000 s.[42]

Insulation resistance respectively the self-discharge constant can be reduced if humidity penetrates into the winding. It is partially strongly temperature dependent and decreases with increasing temperature. Both decrease with increasing temperature.

In electrolytic capacitors, the insulation resistance is defined as leakage current.

Leakage current



The general leakage current behavior of electrolytic capacitors depend on the kind of electrolyte

For electrolytic capacitors the insulation resistance of the dielectric is termed "leakage current". This DC current is represented by the resistor Rleak in parallel with the capacitor in the series-equivalent circuit of electrolytic capacitors. This resistance between the terminals of a capacitor is also finite. Rleak is lower for electrolytics than for ceramic or film capacitors.

The leakage current includes all weak imperfections of the dielectric caused by unwanted chemical processes and mechanical damage. It is also the DC current that can pass through the dielectric after applying a voltage. It depends on the interval without voltage applied (storage time), the thermic stress from soldering, on voltage applied, on temperature of the capacitor, and on measuring time.

The leakage current drops in the first minutes after applying DC voltage. In this period the dielectric oxide layer can self-repair weaknesses by building up new layers. The time required depends generally on the electrolyte. Solid

35	15	1710	9800	460

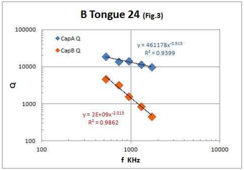
for I = 250 uH and 20pF stray in tank
(Q data in italics is computed)

The quest for high Q is indeed a quest for low ESR as long as you work in the capacitance range needed. One interesting piece of advice I have occasionally seen is that, to increase your tank Q, it is better to use lower-value coils and higher-value tuning caps. As much of the losses in the tank derive from losses in the coil this makes excellent sense. I wish to ask the question what about those higher-value caps? The plot immediately suggests that moving to higher capacitance drives down the ESR, this is a good thing. It may or may not improve the cap Q but I am not sure it matters as long as resistive losses are minimized. To better set my expectations I have again turned to Ben's Cap B data.

The small plot below takes data presented in his Figure 5. Data presented include Q at various capacitances and frequencies. I cross-plotted his data for pF and Q for the appropriate frequencies using both 250 uH and 180 uH inductances. Reading the actual Q off the tiny plot was an estimate at best, but it is interesting. This allows one to estimate his cap Q at any capacitance setting. The table below the likely capacitor data will be specific to caps in the uF range, or 10^6 higher that what we need in a crystal radio tank. Be careful not to get enamored with the high Q values occasionally quoted, check the capacitance. From the plot it should be apparent that not all Q's are created equal. Larger-value caps have lower ESR and so the Q's are often agreeably high. I have plotted a few specific cap measurements from various sources.

Two measurements should stand out; these are indicated by the larger blue diamonds. These are measurements by Bill Hebbert and presented by Ben Tongue in section B of his Article 24. I reproduce his Figure three below, with grateful apologies for the liberties I have taken,

By replotting Ben's figure I can calculate the relation between Q and frequency (table below) and so compute the estimated Q at any frequency. On my main plot I give Ben's Capacitor A and B for 1.0 MHz given the 250 uH inductor. Ben states that the plot assumes 20pF stray added. Since the capacitance needed to resonate at 1 MHz and 250 uH is 101 pF, I make the assumption his caps were set to 81 pF. This accounts for why the diamonds are set slightly off the 100 pF line of the plot. Given his Q measurements it is easy to compute the ESR for each cap. This is the world of the crystal radio builder. I include the ESR at the BCB endpoints for each cap as well to give the full picture.



electrolytes drop faster than non-solid electrolytes but remain at a slightly higher level.

The leakage current in non-solid electrolytic capacitors as well as in manganese oxide solid tantalum capacitors decreases with voltage-connected time due to self-healing effects. Although electrolytics leakage current is higher than current flow over insulation resistance in ceramic or film capacitors, the self-discharge of modern non solid electrolytic capacitors takes several weeks.

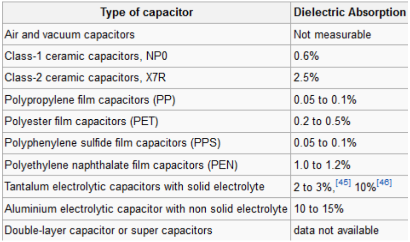
A particular problem with electrolytic capacitors is storage time. Higher leakage current can be the result of longer storage times. These behaviors are limited to electrolytes with a high percentage of water. Organic solvents such as GBL do not have high leakage with longer storage times.

Leakage current is normally measured 2 or 5 minutes after applying rated voltage.

Dielectric absorption (soakage)

Dielectric absorption occurs when a capacitor that has remained charged for a long time discharges only incompletely when briefly discharged. Although an ideal capacitor would reach zero volts after discharge, real capacitors develop a small voltage from time-delayed dipole discharging, a phenomenon that is also called dielectric relaxation, "soakage" or "battery action".

Values of dielectric absorption for some often used capacitors

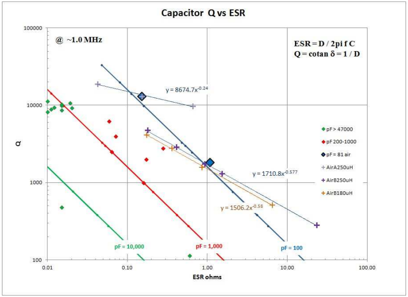


Type of capacitor	Dielectric Absorption
Air and vacuum capacitors	Not measurable
Class-1 ceramic capacitors, NP0	0.6%
Class-2 ceramic capacitors, X7R	2.5%
Polypropylene film capacitors (PP)	0.05 to 0.1%
Polyester film capacitors (PET)	0.2 to 0.5%
Polyphenylene sulfide film capacitors (PPS)	0.05 to 0.1%
Polyethylene naphthalate film capacitors (PEN)	1.0 to 1.2%
Tantalum electrolytic capacitors with solid electrolyte	2 to 3%,[45] 10%[46]
Aluminium electrolytic capacitor with non solid electrolyte	10 to 15%
Double-layer capacitor or super capacitors	data not available

In many applications of capacitors dielectric absorption is not a problem but in some applications, such as long-time-constant integrators, sample-and-hold circuits, switched-capacitor analog-to-digital converters, and very low-distortion filters, it is important that the capacitor does not recover a residual charge after full discharge, and capacitors with low absorption are specified.[47] The voltage at the terminals generated by the dielectric absorption may in some cases possibly cause problems in the function of an electronic circuit or can be a safety risk to personnel. In order to prevent shocks most very large capacitors are shipped with shorting wires that need to be removed before they are used.[48]

dependant. It is important to remember that not all Q's are created equal. What we want is to keep the ESR to a minimum.

On the plot there are a number of data trends presented. Note first that both plot axes are logarithmic, it makes a difference on how one thinks of the data. Additionally, note that the plot is specific (mostly) for data at 1.0 MHz. I make the assumption that a cap that is superior at that frequency is likely to be superior across the BCB.



The first things to discuss are the three slanting lines. These are computed from a table of Dissipation Factors at 1.0MHz by Dr. Johnson. I have supplied the capacitances and calculated the resulting Q and ESR values. When one goes looking at capacitor data sheets or summary tables one is likely to find data computed at 100 KHz and 1.0 MHz (mercifully) but that

Crystal Radio Capacitors and ESR

Kevin Smith

In my ongoing effort to understand crystal radios and the theory that makes them work I have recently turned to setting my expectations concerning capacitance. The tuning capacitor is, next the coil itself, the principal component of the set. Few builders fabricate their own tuning caps so I suppose it is possible to take them a bit for granted. I have been reading on the radio forums some threads concerning radio Q and the subject of the variable cap Q seems to be getting more attention. So, what is the deal?

I set about my study by gathering what I could find on the web and at the close of this note I include a short reference list of useful pages from which I extracted data the ideas. I wish to extend special thanks to Ben Tongue who, as usual, has provided the essential measurements and background. The plot below of capacitor Q versus Equivalent Series Resistance (ESR) summarizes my findings. It is a bit busy as there are a number of interesting and important ideas represented in the relationships presented.

Any discussion of component quality needs first to acknowledge that the fight to increase the component Q is in reality a fight to eliminate (not possible) or reduce as much as feasible the resistive losses associated with that component. It helps then to look not just at Q, but at how Q relates to the component ESR. There are two fundamental equations that describe this relation: 1) Q = cotan theta = 1/D. D is the dissipation factor and is an attribute of the dielectric material used in the construction of the capacitor. Equation 2) ESR = D / 2pi f C. This equation tells us that capacitor losses expected due to resistance are both angular frequency and capacitance

Sensitivity and selectivity issues in crystal radio sets including diode problems; measurements of the Q of variable and fixed capacitors, RF loss in slide switches and loss tangent of various dielectrics

By Ben H. Tongue
http://www.bentongue.com/xtalset/20MeaAGs/20MeaAGs.html

Part A: The Issues.

The sensitivity and selectivity in a crystal radio set can be impacted by many factors, including:

- A1: Ineffective coupling of the antenna to the tank circuit.
- A2: Resistive RF losses in the tank circuit.
- A3: Inappropriate diode.
- A4: Unintentional diode damage from exposure to electrostatic discharge (ESD) or voltages higher than the minimum reverse voltage rating. This is one cause of the loss of weak-signal sensitivity over time.
- A5: Relations between antenna-ground system, diode RF input and tank loss resistance, as effecting selectivity and loaded Q.
- A6: Audio transformer loss.

A1. There is a practical minimum limit to the possible impedance transformation ratio of the series resistance of the antenna-ground circuit to the shunt value desired across the tank circuit, when the transformation means is just a series capacitor between the antenna and the top of the tank. This problem occurs when the capacitor required for the desired

Do you really want a linear ohm meter scale? How about a LOG scale? Analog or digital?
What are the reasonable good and bad limits of ESR? What range in ohms? How sensitive does it need to be?
Input - To protect or not protect? What about charged caps?
Power - Battery or A/C adaptor? Battery life?
Physical Size
Cost

All of the above choices were carefully considered in the design of the Capacitor Wizard®. The end product was to be easy to use, durable, small & lightweight, accurate, measure ESR in circuit and inexpensive. I think I have met these design goals with the Capacitor Wizard®!

impedance transformation becomes so large that it causes the tank inductance to resonate below the desired frequency (See Article #22, Part 2). The solution here is to use a lower value inductance for the tank or to tap the antenna down on the tank (towards ground). This is why some experimenters find that low inductance tank circuits seem to work better than those of higher inductance. If one does not use a series capacitor for impedance transformation, the antenna may be just tapped down on the tank. Another alternative is to connect the antenna-ground system to a low value unturned inductance that is coupled to the tank.

The main advantage of using a series capacitor connected to the top of the tank (for impedance matching) is that it moves the undesired short wave resonance of the antenna-ground circuit (present in every single tuned crystal radio set) to the highest possible frequency and reduces its strength. A disadvantage is that unless a high enough Q variable capacitor is used, insertion power loss is increased, especially at the high frequency end of the band. See Part B, Section 1 of this Article and Article #22, Part 7.

A2. Resistive RF losses in the tank circuit are affected by: 1) Losses in any capacitor used for tuning or RF coupling. 2) Physical size of the coil and such items as length/diameter ratio, cross-section size and shape, and turns spacing (to reduce coil proximity losses). 3) Loss tangent in the coil form material, wire insulation and all dielectric material penetrated by the electric field of the coil. 4) Wire size and plating, if any. Silver plating is good but tin plating is bad, especially at the high end of the band. 5) Wire construction such as litz, solid or un-insulated stranded. The latter should be avoided. 6) Switches (if used). 7) Magnetic coupling from the coil to nearby lossy metallic objects. 9) Capacity coupling from "hot" high impedance RF points through a lossy RF return path to ground. See Article #22, point 7 of Part 10. Some comments: The loss from the loss tangent of the dielectric material used for the mounting base of detector stands can be nontrivial. Loss tangent of the material used for a front panel can cause dissipative loss if terminals provided for the connection of an external diode are too close together. See Part B, section 3 of this Article.

A3. A diode with too low an axis-crossing resistance (too high a saturation current) will resistively load the tank too heavily, causing a low loaded Q that results in loss of selectivity and sensitivity. A diode with too high an axis-crossing resistance (too low a saturation current) will increase selectivity because it only lightly resistively loads the tank circuit. The disadvantage is that sensitivity is reduced (many people liken this to the diode having too high a "turn-on" voltage.) and considerable audio distortion is generated. A little reverse or forward DC voltage bias will usually fix up these performance problems. See Article #9.

A way to check whether weak signal performance would be improved if one used a diode with a different saturation current (Is), but without experimenting with DC bias, is as follows: 1) Give the diode a one second or so spray with an aerosol "component cooler" . The reduction in temperature will temporarily substantially reduce the Is of the diode. If performance improves during the subsequent warm-back-up period, but before reaching room temperature, the diode has too high a room temperature Is. 2) Heat the diode by holding a hot soldering iron next to it for 5 seconds or so or give it a quick blow from a hot hair dryer. If performance improves during the subsequent cool-back-down period, but before reaching room temperature, the diode has too low a room

voltage across the test terminals to maintain its constant current. This voltage would turn on solid state devices when measuring ESR in circuit. For this reason the constant voltage method was chosen for the Capacitor Wizard.

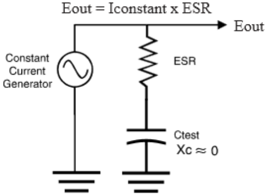
For convenience we don't want a linear scale because it would require a Range Switch. I modified the basic constant voltage diagram above to include a resistor in parallel with the constant voltage generator that has the desirable effect of logging the ohm scale. It also serves to lower the output voltage to a level far below that required to turn on solid state devices.

Conclusion:

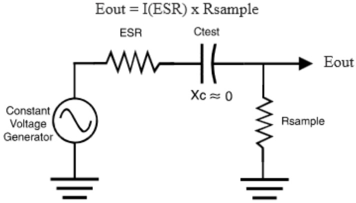
It should now be obvious that a DC ohm meter cannot measure ESR! A Capacitance meter is equally unsuitable for ESR measurements. ESR doesn't exist under the STATIC measurement condition of a DC ohm meter. Capacitance tells one nothing about a capacitors ESR. To measure ESR a controlled DYNAMIC test condition must be created. To create this test condition the engineer needs to consider a number of "Design Judgement Calls" based upon his experience and the desired end result. Electronic design is an exercise in compromise. There are many ways to design an ESR meter and each has its advantages and disadvantages. The quality of the end product is the result of wise choices made by the design engineer. Some of the important design considerations for an ESR meter are:

Which to use - constant voltage or constant current? At what magnitudes?
Test Signal - Sine wave or square wave? At what frequency?

with a linear meter scale. We could use either digital or analog meter displays.



Constant Current Method



Constant Voltage Method

Constant current has the advantage of conveniently measuring low values of ESR down in the milli ohm range. It however has the disadvantage of applying a theoretical infinitely large

temperature Is. Is, for the usual Schottky diode, changes by about two times for each 10° C. temperature change. Germanium diodes probably act the same. Aerosol component coolers are available from most Electronics Distributors, including Radio Shack.

A4. Semiconductor diodes are subject to damage from exposure to electrostatic discharge (ESD) and voltages higher than their reverse breakdown values. Easy-to-check-for damage shows up as an increased reverse current when tested with a reverse DC voltage close to or less than the specified minimum breakdown voltage, as compared to an undamaged diode. Other types of damage can also occur. The effect on detector performance can be anywhere from a mild to a very great reduction of weak-signal sensitivity. This type of damage has the effect of placing a resistor across the diode, which reduces tank Q and adds a parasitic, unneeded audio load resistance. If one has an old VOM having a d'Arsonval moving-coil meter movement (not a digital type) such as the Triplett 360, Weston 980 or Simpson 260, one can do a quick check of the back leakage of a Schottky diode by measuring its back resistance on the X1,000 range. If the needle does not move, the diode has probably not been damaged from ESD. This test does not apply to so-called zero-bias Schottky detector diodes because of their usual low reverse breakdown voltages. Undamaged germanium diodes normally have greater reverse leakage (lower back-resistance) than the usual Schottky detector diodes. This does not effect performance in crystal set applications. The germaniums seem less subject to the electrostatic damage problem precisely because their lower back-resistance (and high reverse breakdown voltages) tends to bleed off any electrostatic charge that might accumulate, maybe from handling. Diodes with the lowest leakage can be selected with a simple test as follows: Connect a 3-4.5 volt

DC source, a 4.7k to 10k resistor, the diode and a DVM set to read DC current in series. Polarize the battery so that the diode is back biased. If the current is 2 uA or less, the parasitic back leakage resistance is greater than 2 Megohms or so and all should be well, as far as weak signal loss is concerned. The resistor is used to prevent damage to the test diode if it is accidentally connected in the forward direction. This test may be used to sort out the best weak-signal sensitivity diodes and exclude damaged ones. It is probable that for a selection of diodes having the same part number, ones with the lowest reverse leakage current will deliver the best weak-signal performance.

I believe poor weak-signal results some people have reported with the Avago (formerly Agilent) 5082-2835 and HSMS-2820 diodes can be laid at the doorstep of ESD damage. I experienced my first problem with these diodes by storing a few new ones in a propylene vitamin pill bottle for a while. When I wanted a new one I picked up the bottle, shook it (I think,) to see if something was inside and withdrew a diode. It performed badly, so I checked its back resistance with my Triplett 360 VOM as suggested above and found a low back resistance reading. Checking all the others, I found they were all bad. Static electricity did them in... beware! It was pretty stupid of me to not use anti-static bags. BTW, I've never had problems with those diodes if stored in paper bags. The bags must have had enough moisture content to provide sufficient conductivity to bleed off any static charge that might accumulate.

It is difficult to properly impedance match these diodes (see Part 4 of Article #5) because of their low saturation current (high axis-crossing resistance). They work best if 3 or or so are connected in parallel to raise the effective saturation current. If

---

Disadvantages: Not suitable for in circuit use, will not find open caps, keying must be highly accurate and short duration or ESR readings will be wrong, moderately complex, moderate cost, requires periodic calibration

We now have a method to correct for capacitive reactance by using a high test frequency and a valid formula to compute ESR. Let's investigate our formula E=IR.

The formula E = IR has three unknown quantities and it is not usable until we get the formula into the form of two known and one unknown quantities . The quantity we are trying to find is "R" so let's make it the unknown. We are left with "E" (voltage) and "I" (current) as the two variable quantities to be measured. Using conventional test equipment we can drive a capacitor with an ac 100khz signal, measure both "E" and "I" and, using the formula E = I x R, compute "R" (ESR). That method will work but it is clumsy, slow, and requires two pieces of test equipment - an AC volt meter, and an AC ammeter. If we were to hold one of the two variables in the test signal at a known CONSTANT VALUE we could measure the other variable with only one piece of test equipment! We could then calibrate its scale to represent the COMPUTED VALUE of "R"!! We could hold the test signals current(I) constant and measure the voltage(E) and then use the result to compute the value of "R". Or we could hold the test signals voltage(E) constant (the Capacitor Wizards method) and measure the test signals current(I). The result could be displayed on an analog or digital meter calibrated in ohms. These two methods of measuring resistance are well known by electronic measurement engineers as the "CONSTANT CURRENT" and "CONSTANT VOLTAGE" methods. Since the formula E = IR is a linear expression, both methods will yield an ohm meter

(1) Use a high test frequency: This is the technique the Capacitor Wizard® uses to "Zero Out" capacitive reactance.

Advantages: Will find open capacitors within the specified range of capacitance, Simple circuit, Reasonable Cost, no calibration required

Disadvantages : Only valid above a certain capacitance value, dependent upon test frequency

Xc = capacitive reactance
Zc = Total AC resistance (Vector Sum of Xc and ESR)
ESR = Equivalent Series Resistance
C = capacitance in Farads
F = Frequency in Hertz

Proof:

$$\text{If} \quad Xc = 1 / (6.28 * F * C) = 0 \quad \text{AND} \quad Zc = \sqrt{ESR^2 + Xc^2}$$

$$\text{THEN} \quad Zc = \sqrt{ESR^2 + 0^2} = \sqrt{ESR^2} = ESR$$

(2) Electronically subtract capacitive reactance from measured AC ohms:

Uses: Suitable for capacitor manufacturer

Advantages: Measure ESR of any capacitor, can also be adapted to measure capacitance

Disadvantages: Requires operator skills, not suitable for in circuit use, circuit complex, cost more, easily damaged, will not find open capacitors, requires periodic calibration

(3) Sample/Hold Keying:

Uses: Inexpensive method to measure ESR of any capacitor

Advantages: Measure ESR of any capacitor

---

one wishes to use only one of these diodes, it could have a low forward bias applied to get the same result (see Article #9). Keep in mind that these diodes do not do very well on strong signals when optimally impedance matched for weak signal reception because of their low reverse voltage breakdown rating. Avago specifies that rating as 15 volts for these diodes. If a rectified voltage approaching 7.5 volts appears across the DC load (now operating in 'peak-detector' mode), a maximum reverse voltage of about 15 volts will appear across the diode for every cycle of the RF carrier. When the diode is operated at this signal level or greater, a 'bucking' rectified current flows through the diode reducing audio output and causing audio distortion. This problem is eliminated by using diodes having a greater reverse breakdown voltage such as most ITT FO 215 and most 1N34A units.

A5. A question asked by many designers is this: What is the best approach when deciding how to 'impedance match' the transformed antenna-ground-system resistance to the RF input resistance of the diode detector? This would be a no-brainer if the resonant resistance of the tank was infinite, but it is not.

Table 1 - Definitions of Terms

IPL	Insertion power loss
Lo	Inductance of the tank
Ql	Loaded Q of the tank
Qo	Unloaded Q of the tank
Rag	Actual antenna-ground-system resistance
Ragt	A antenna-ground-system resistance transformed its value at the top of the tank
Rd	Actual input RF resistance of the diode.
Rdt	Input RF resistance of the diode as transformed to its value at the top of the tank.
Ro	Resistor representing all losses in the tank
Xa	Antenna-ground-system impedance transformation.
Xd	Diode input RF resistance transformation.

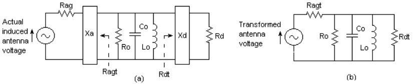


Fig. 1 - Simplified schematics of a single-tuned crystal set.

Simplified Schematic

The presence of finite tank loss increases IPL from the theoretical zero of the matched impedance case. It also reduces selectivity. Fig. 1a shows a simplified schematic of a single-tuned crystal radio set. The input impedance transformation Xa might take the form of capacitor in series with the 'Rag' and the 'induced voltage source' series combination or a tap on the tank. The diode input RF resistance transformation might take the form of a tap on the tank or a capacitor in series with the diode, along with other components. See Son of Hobbydyne and Hobbydyne II at http://www.hobbytech.com/crystalradio/crystalradio.htm. Table 2 shows calculated data for the simplified schematic shown in Fig.1b.

Table 2 - Calculated Insertion power loss (IPL), ratio of loaded to unloaded Q and impedance match (return loss*) in a single-tuned circuit.

---

does not really exist as a physical entity so direct measurements across the ESR resistor are no t possible! However, if a method of correcting for the effects of capacitive reactance is provided, and considering all ESR resistances are INPHASE, ESR can be calculated and measured by using the basic electronics formula E = I x R! This is the Basic Electronics foundation used to design the Capacitor Wizard®!

Before the formula E = I x R can be used to compute ESR, we must find a way to "ZERO OUT" or otherwise negate the effects of capacitive reactance. Here's why: Consider a series AC circuit that has an equal capacitive reactance (Xc) and resistance (ESR) of 10 ohms. The total value of these resistances when measured with an AC ohm meter will be the "VECTOR SUM" of the CAPACITIVE REACTANCE and the INPHASE resistance measured in ohms. In this example the total resistance measured by the AC ohm meter will be 14.14 ohms! This vector sum is always larger than the INPHASE resistance(ESR). For this reason an AC ohm meter is not a valid device to measure ESR unless a means of negating the effects of capacitive reactance is applied. Three equally valid basic techniques come to mind: (1) Raise the AC ohm meters test frequency so high that the capacitive reactance is so low compared to the expected ESR that the effects of capacitive reactance can be ignored. (2) Electronically subtract the capacitive reactance portion of the vector sum from the total measured AC resistance. (3) Use a sample/hold keying circuit and only "key on" the AC ohm meter when the PHASE ANGLE between the measured AC resistance and the test signal is at 0 or 180 degrees (INPHASE). Each technique has its advantages and disadvantages which will be explained below.

Capacitor ESR - Methods of Measurement

by Doug Jones (Capacitor Wizard)

http://www.midwestdevices.com/pdfs/Tnote3.pdf

E = I x ESR

ESR would be easy to measure if it really existed as the single physical resistor represented by the drawing above! Unfortunately you can't just hang two test leads across the ESR resistor in the drawing above and measure the ESR! The drawing is just a symbolic representation of the total effect of the many physical quantities that make up ESR! This article is intended to give the reader an understanding of ESR and an introduction into the complexities of measuring ESR.

ESR is a DYNAMIC quantity of a capacitor. ESR does not exist as a STATIC quantity therefore it cannot be measured by a conventional DC ohm meter. ESR exists only when alternating current is applied to a capacitor or when a capacitors dielectric charge is changing states. ESR can be considered to be the TOTAL INPHASE AC resistance of a capacitor. INPHASE means the current(I) and the voltage(E) if measured across the resistive component ESR(R) of a capacitor are INPHASE with each other, just as if ESR(R) were pure resistance (no capacitive or inductive reactance). ESR includes the DC resistance of the leads, DC resistance of the connections to the dielectric, capacitor plate resistance, and the INPHASE AC resistance of the dielectric material at a particular frequency and temperature. The combination of components that make up ESR are symbolized by a resistor in series with a capacitor as shown above. This symbolic resistor

*Return loss is a measure of the "goodness" of an impedance match. A value of minus infinity indicates a 'perfect impedance match' (all the available input power is delivered to the load). A value of zero indicates a 'perfect impedance mismatch' (all of the available input power is reflected back to the source, and none is delivered to the load). An intermediate value indicates the amount of available power that is reflected back to the source by the load. The usual way of referring to mismatch of a two-port network is by using S parameters. S11 is the input reflection coefficient and S22, the output reflection coefficient. The magnitude of a voltage reflection coefficient is 20*log|{(Rload-Rsource)/(Rload+Rsource)}|. One reference is Radiotron Designer's Handbook, Fourth Edition, pp 891-892. In our case, consider out little circuit (at resonance) to be a zero length transmission line having attenuation. Note that the Handbook was written before 'S" parameters were widely used.

Table 1 shows the tradeoff between IPL and selectivity. The lower Rag and Rd become, the lower IPL becomes, but Ql/Qo drops (poorer selectivity). Higher values of Rag and Rd result in greater IPL and greater Ql/Qo (greater selectivity). Ramon

Vargas has suggested that many people consider the parameters on line 4 to be close to a practical optimum, and they are. Line 3 shows alternate parameters for achieving the same selectivity at an IPL 0.51 dB less. A general rule may be stated that for any given value of Ql/Qo, equal values for Rag and Rd will result in the least possible IPL. In this case, input and output return losses will be equal. It appears to me that the parameters in lines 3 or 6 are probably the ones to shoot for in most design calculations.

An effect I have observed is that one cannot simultaneously attain a perfect impedance match at both input and output ports in systems of the type shown in Fig. 1a (simultaneous conjugate match). As shown on lines 4 and 5 in Table 2, Ragt and Rdt can be arranged to provide a perfect match at one port, but then the other port will be mismatched. Ro could be replaced by a series resistor (not a real-world crystal radio set anymore) and one would still not be able to arrange a simultaneous impedance match. If circuit losses were represented by proper values of both series and shunt resistances, it would then be possible to attain a simultaneous perfect match at both input and output.

An audio transformer is one passive device that has series and shunt loss components. If it is so designed, it can provide a simultaneous perfect impedance match at both input and output when loaded by its designed-for load resistances (ignoring reactance effects). If operated at any other impedance level, such as doubling the source and load resistances, simultaneous perfect input and output impedance matching cannot be attained. This info is of mainly theoretical interest for most crystal radio set applications except when one tries to operate an audio transformer at considerably higher or lower source and load resistance values than it was designed

Part B: The Measurements.

Loss measurements at various frequencies on some components, with the loss expressed as a parallel resistance (Rp) in parallel with the capacitance of the component or the loss tangent, or equivalent Q of the component:

*

B1: Q and equivalent parallel loss resistance (Rp) of two variable capacitors vs frequency when resonated with a 250 uH inductor, in parallel with a total circuit stray circuit capacitance of 20 pF. Rp and Q vs. frequency at four different capacitance settings is also shown.

*

B2: Equivalent parallel loss resistance of some DPDT slide switches.

*

B3: Loss tangent of some coil form and sheet plastic (front panel) materials.

*

B4: Q of inductors and L/C resonators.

*

B5: High Q fixed value ceramic capacitors.

B1: Measurements at 520, 730, 943, 1300 and 1710 kHz, made on two different variable capacitors used in crystal radio sets, are shown in the two graphs below. Capacitor A is a 485 pF variable capacitor that was purchased from Fair Radio Sales. It has a ceramic insulated stator and silver plated brass plates with silver plated wiper contacts. Capacitor B is a small 365 pF air-variable capacitor purchased from the Xtal Set Society. Its plates are made of aluminum and the stator support insulators are made of a phenolic plastic. This capacitor is similar to those sold by Antique Electronic Supply and others. See note at the end of this section B1.

Fig. 2 shows Rp plotted against frequency, with the capacitor adjusted at each frequency to a value 20 pf lower than that required to resonate a 250 uH inductor. This allows for a stray capacitance of 20 pF, in an actual circuit. Any losses that may be in the stray capacitance are assumed assigned to the inductor. The plot shows how, in actual practice, the Rp of variable capacitors A and B vary when tuned across the broadcast band. Fig. 3 shows how the Q of the total capacitance (including the 20 pF stray capacitance) varies across the BC band for each capacitor. Do not make the mistake, when looking at the two graphs below, of thinking that they represent Rp and Q of capacitors A or B vs. frequency, with the capacitor set to a fixed capacitance. The capacitance is varied as a function of frequency, along the horizontal axis of the graphs, to a value that would resonate with a 250 uH inductor. Figs. 4 and 5 show Rp and Q of capacitor B as a function of frequency, at four different fixed capacity settings (the frequency at each capacitance setting is always a value that brings about resonance with the 250 uH inductor).

The higher loss of this capacitor compared to that of the variable capacitor can be partially attributed to the difference in conductivity – copper versus silver, but this would give a difference of only about 6-7%. The additional loss is probably due to the longer conducting path in the fixed capacitor, because the connection to the outer tube was half way down its *outside* surface, so current to the inside had about twice the distance to travel. It became clear that even if the conductors were silver plated and the construction changed to minimise the conduction path it was unlikely that a loss significantly lower than the variable capacitor would be achieved, which was the aim.

If the plate is silver (as here) , then p=1.629 10-8, and u = 4pi10-7, so Zwall = 8 10-4 at 10 Mhz. Evaluating ***l*** and w is somewhat difficult, but if we take semicircular plates of radius r, then when the capacitance is maximum the rotor and stator plates will fully overlap. The average length from the centre of the rotor (where current enters) will be r/2 and the average width (taken as the average circumference) will be 2π(r/2)/2, so the ratio ***l*** / w will be 1/π. As the spindle is rotated the overlap between the rotor and stator will reduce in direct proportion to the capacitance, so ***l*** / w will vary as:

$$\boldsymbol{l} / w \approx 1/(\pi\ C/Cmax) \qquad \text{A1.2}$$

So at maximum capacitance we can expect the loss resistance in the plates to be, Rv = 2 Zwall / (πN) = 0.034 mΩ at 10Mhz, for N=15. This is a factor of around 1000 less than that measured, and so any variation with spindle rotation would be insignificant, and as experiment confirms.

Appendix 2 : Standard Capacitor

An attempt was made to produce a standard capacitor, having a very low loss. This was made using two coaxial copper pipes, 15mm and 22mm diameter, about 100mm long. The insulation between the two pipes was two bands of PTFE tape, located at the ends of the tubes. Capacitance was around 25pf.

However this capacitor had a lower Q than the variable capacitor by about 12%. It was thought the PTFE tape may be lossy (it was plumber's tape), and it was replaced with thin expanded polystyrene foam, but with the same results.

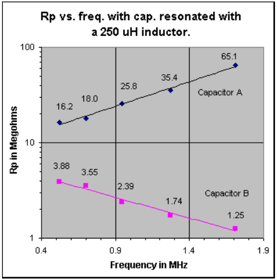

Fig. 2

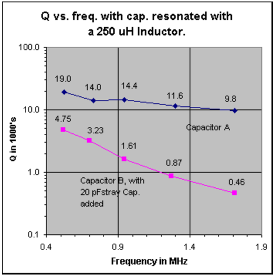

Fig. 3

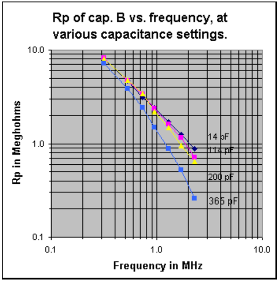

Fig.4

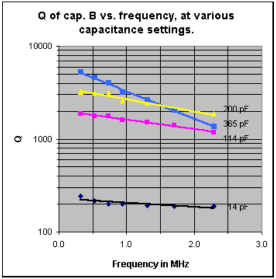

Fig. 5

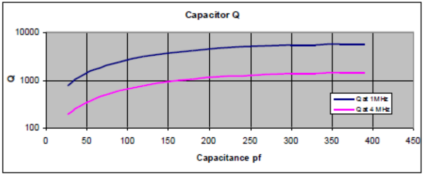
capacitor uses a relatively inexpensive insulator, such as porcelain with a loss tangent of 0.0075, then the capacitance of its insulators is 4.8 pf (see Section 8.5), around half the minimum capacitance.

The contact resistance is also seen to be much larger at 32 mΩ compared with 10 mΩ. However, the metallic loss is about 1/3rd that of the Photo 1 capacitor (0.0039 cf 0.01), despite the metalwork being aluminium rather than silver. This lower metallic loss is because of the very much shorter path which the current takes. Its Q at 1 MHz and 4 MHz is given below :



Appendix 1 : Estimated Loss in the Plates

The resistance of two plates will be twice that of one plate, and if we have N pairs of plates the resistance Rv will be :

Rv = 2 Zwall ***l*** / (N w) A1.1

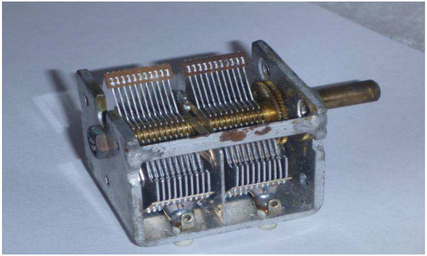
where Zwall = p /d = (p d u f)0.5
p is the resistivity of the metal
u is the permeability of the metal
l is the length of the current path through the plate
w is the width of the current path through the plate

Subsequent to the above work, the loss of the broadcast-band tuning capacitor shown below was measured, and gave the following equation for its series resistance:

$$Rcap = 0.032 + 5800 /(f\ C2) + 0.0039\ (f\ 0.5)\ \text{ohms} \qquad 10.1$$

where f is in MHz and C in pf

The accuracy of the above equation is estimated at ± 13%.



Photograph 3 : Broadcast-band Capacitor

This capacitor has 2 sections each with a range of 10 pf to 380 pf, and the above equation is for one section.

It is interesting to compare the losses of the capacitor shown in Photo 1 with that of this broadcast-band capacitor. In common with most capacitors of this type it has a very short insulation path and this accounts for the high dielectric loss factor of 5800 in the above equation, over 7 times the loss of the capacitor shown in Photo 1. Assuming this broadcast-band

---

Discussion:

There are two main sources of loss in an air-dielectric variable cap: 1) Loss in the dielectric of the stator insulators, and 2) Resistive losses in the metal parts. Of course, there is also the important very low-loss capacitor made from the air dielectric between the plates. The losses in 2) include resistive loss in the plates and in the wiper that connects the rotor to the frame. Resistive loss in the plates is very small at low frequencies, but increases with increasing frequency because of skin effect.

Notice, that for capacitor B, Rp (vertical scale) in Fig. 4 is about the same for all capacitance settings at the lowest frequency plotted (310 kHz). Rp is approximately constant over the full 14-365 pF capacitance range. This is because we are varying a high Q air dielectric capacitor of very low loss, in parallel with a low Q fixed capacitance made up of the lossy phenolic stator supports. Most of Rp comes from the loss in the phenolic. In Fig. 5, again at the low frequency end of the horizontal axis, observe that Q is a direct linear function of the overall capacitance, as it should be. The Q of the air-variable part, taken alone, is much higher than that of the capacitor made up of the phenolic insulators. The main loss, here, comes from the approximately fixed shunt Rp provided by the phenolic stator supports. At 14 pF the C from the air cap is relatively low compared to that from the phenolic insulators. At 365 pF the C from the air cap is much higher than that from the phenolic supports.

Things change at higher frequencies. The reactance of the capacitor drops. This, combined with the series resistance of the plates and wiper now come into play as an additional factor reducing the Q. If this series resistance (Rs) were the only resistance affecting Q, the equation for Q would be: Q=(reactance of the capacitor)/Rs. One can see from this equation that the introduction of Rs makes the Q drop when frequency increases. Up to now, the main loss came from the parallel loss resistance of the phenolic supports. The Q from a setting of 365 pF drops quite rapidly with increase of frequency because of this series resistance. Skin effect makes the effect worse by increasing Rs, the higher one goes in frequency. Notice that at the low frequency end of Fig. 5, Q is approximately proportional to the capacitance, as it should be if the main loss is the fixed shunt resistance Rp, coming from the phenolic stator insulators.

Fig. 5 shows an approximately constant Q (vs. frequency) when the capacitor is set to 14 pF. The loss causing this low, constant Q, comes from the loss tangent of the capacitor formed from the phenolic stator insulators. At low frequencies, Q increases when the capacitor is successively set to 114, 200 or 365 pF because engaging the plates adds a high Q air dielectric capacitor component in parallel with the low Q capacitor formed from the phenolic dielectric supports. As frequency increases, with the capacitor set to 365 pF, one can see that the Q drops at a faster rate than it does when set to 200 or 114 pF. This is because Rs (being in series with the air capacitor, that dominates at the 365 pF setting), acting with its lower capacitive reactance results in a capacitor of lower Q (Q=reactance of air capacitor at 365 pF/Rs).

In the Figs. 2 and 3, the capacitor is always set for a circuit capacity value that resonates with 250 uH. This means that at 520 kHz, the varicap is set so the circuit capacity is 375 pF. At 1710 kHz, the circuit capacity is set to 34.7 pF. Even though the capacitor Q goes from 19,000 to 9800 as frequency goes from 520 to 1710 kHz, Rp increases as frequency increases

The series resistance of a variable air capacitor at radio frequencies is shown to be given by :

Rcap = Rs + α /(f C2) + β (f 0.5) ohms 9.1

where Rs , α and β are constants for any particular capacitor.

f is the frequency and C the capacitance

The first factor Rs is due to the contact resistance, and this is largely due to the wiping contacts. The second factor is due to the dielectric loss in the supporting insulator, and the third factor is due to the resistivity of the metalwork, particularly that supporting the plates.

Measurement of this resistance requires the capacitive reactance to be tuned-out with a low loss inductor and it is shown that this can be achieved with straight copper pipes arranged as a shorted two-wire transmission line.
For the capacitor shown in Photo 1, the series resistance is given by:

Rcap = 0.01+ 800 /(f C2) + 0.01 (f 0.5) ohms 9.2

where f is in MHz and C in pf

The accuracy of the above equation is estimated at ± 13%.

10. ANNEX 1 : BROADCAST CAPACITOR

In respect of dielectric loss, Jackson says ‘The overall capacitance C of the capacitor may be regarded as composed of a fixed and imperfect portion C1 due to the supporting insulation, in parallel with a variable air portion devoid of energy loss. The power factor tan δ of the portion C1 seems usually to be substantially constant over a wide frequency range’.

It is interesting, although not particularly useful, to calculate capacitance of the supporting insulation, C1. This can be determined from Equation 6.1.2, by setting C = C1, since then the loss is not diluted by the air capacitor and the series resistance due to the dielectric loss will then be :

$Rc = 800/(f\ C12)$ 8.5.1

Also from the definition of tan δ :

$Rc = \tan\delta/(2\pi f\ C1)$
for f in Hz and C in farads

$= 106 \tan\delta/(2\pi f\ C1)$ 8.5.2
for f in MHz and C in pf (as equation 8.5.1)

Equating 8.5.1 and 8.5.2 :

$C1 = 2\pi\ 800 / (106 \tan\delta)$ pf 8.5.3

The material of the insulator is unknown but is possibly Steatite, for which tan δ = 0.003, and then the capacitance C1 due to the supporting insulation is 1.7 pf.

9. SUMMARY

---

because the circuit capacity must be reduced from 375 to 34.7 pF to tune the tank from 520 to 1710 kHz (Rp=Q/(2*pi*f*C).

If the question is posed: 'Is it more important to have ceramic insulated stators or silver plated plates on a variable capacitor used in a BC band crystal radio set?', the answer is that ceramic insulated stators are the way to go.

Capacitor A: The main practical conclusion that can be taken from Fig .2 above is that Rp of capacitor A is very high over the whole band and varies roughly proportionally to frequency, over the frequency range of interest: 520-1710 kHz In fact, Rp is so high that it will not contribute any appreciable loss even when used in high performance crystal radio sets using a high Q tank inductor. Another plus is that its Rp increases with increasing frequency, further reducing any effect on loaded Q, sensitivity or selectivity at the high end of the band. The silver plating on the brass plates is beneficial because the resistivity of silver is about 25% of that of brass. Practically speaking, the silver should have little effect on the operation of a crystal radio set in the BC band, but short wave is another matter. The Q of the capacitor drops at higher frequencies, especially when set to a high capacitance value. Silver plating can materially improve performance at higher frequencies by providing a needed higher Q. Be aware that some capacitors are made with cadmium plated brass plates. Silvery-whitish colored cadmium has a resistivity 4.6 times that of silver. This higher resistivity will somewhat reduce Q at high frequencies and at high capacity settings. Some people mistakenly assume, because of the silvery-whitish color, that cadmium plated plates are really silver plated.

Capacitor B: One can see from Fig. 2 that Rp of capacitor B varies approximately inversely with frequency. The DLF (dielectric loss factor) of the phenolic stator support insulators is the main cause of this loss, over the whole frequency band. Towards the high end of the band, some loss is contributed by the series resistance in the capacitor plates, the rotor shaft wiper contact and skin effect. This loss effect is greater than that in capacitor A because the resistivity of the aluminum plates is 1.7 times that of silver. Practically speaking, this effect is minimized at the high end of the band because the plates are mostly disengaged. The Rp of the capacitor will have its greatest effect in reducing sensitivity and selectivity at the high frequency end of the band because that is where its value is the the lowest. See note at the end of this Article.

The usual crystal radio set uses shunt capacitor tuning with a fixed tank inductance. This configuration causes the tank reactance to be highest at the high end of the band, thus further reducing loaded Q, sensitivity and selectivity, for a given value of Rp. At the low and medium frequency parts of the band, Rp of the capacitor is so high that its effect is small in many crystal radio sets. Highest performance crystal radio sets made with high Q inductors, with careful attention to impedance matching may experience a noticeable reduction in sensitivity and selectivity at the high end of the band when using this or other capacitors using phenolic stator insulation. This is because the Rp of the capacitor becomes comparable to the higher equivalent Rp of the high Q tank inductor at the high end of the band as compared to its value at the low end. To clarify this, an ideal condition would exist if Rp of the capacitor and inductor were infinite. If this were to be the case, and good impedance matching of antenna-ground system to tank, diode to tank and headphones to diode existed, all of the power intercepted by the antenna-ground system would be delivered to the headphones and maximum sensitivity would occur. Any loss present in capacitors, inductors or

remaining 30% is grooved. So we might anticipate the loss increasing considerably, and if it is assumed by a factor of 4, to 12 mΩ, this agrees well with the measurements as the following shows : a similar situation exists for the moveable vanes, and they are supported by the central spindle and this has very deep grooves. So by the same argument its resistance is estimated to be 15 mΩ, giving a total due to metallic loss of 27 mΩ, close to the measurements of total metallic loss of 28 mΩ at 10 MHz.

So it seems that the current flow in the support pillars is seriously interrupted by the presence of the plates, and this is a major source of loss.

8.4. Conductor Loss Budget

Bringing together the estimated conductor losses discussed above gives the following for 10 MHz (all figures are very approximate) :

Loss in vanes	0.03 mΩ	i.e. negligible
Pillar supporting static vanes	12 mΩ	
Shaft supporting moving vanes	15 mΩ.	
Slip ring contact resistance	10mΩ.	
Two solder tags	1 mΩ	
Total	38 mΩ	

The measurements indicate a total of 42 mΩ, so the above seems a reasonable estimate.

8.5. Dielectric Loss and Capacitance of Plate Supports

leaving about 4.5 mΩ attributable to each of the sliding contacts. This is somewhat larger than Bock's measurements (ref 4) of contact resistance of silver contacts of 1 mΩ, but the contact force here may be lower than his 100 gm, and also the contacts could be worn.

8.2. Loss in Plates

There is no indication in the measurements that the loss varies with capacitance setting, and so the loss in the plates is presumably very small, and this is supported by the analysis given in Appendix 1. Field & Sinclair (ref 3) found the same and stated 'the change in series resistance with rotor displacement is therefore small despite the change in current distribution in the plates'.

8.3. Loss in Plate Support Pillars

The static plates are supported by two silver-plated cylindrical bars, which are bolted to the end ceramic. If only one pillar is connected to the external circuit (the normal configuration), then the whole of the current flows through this pillar. Its diameter is 6.5 mm, and it has an effective length of 70 mm, and at 10 MHz such a bar would have a resistance of around 3 mΩ, assuming the whole circumference carries current. However part of the circumference is interrupted by the plates, and these will seriously affect the current flow. To see this, imagine a cylindrical conductor with circular washers along its length, forming a structure similar to a thermal radiator. Current flowing from one end to the other will now have to flow outwards across one face of each washer, across its thickness, and down the other face, and this will increase the resistance considerably. In the capacitor here, around 70% of the circumference is interrupted by plates and in addition the

transformers reduces sensitivity. In this discussion we are dealing primarily with losses in the resonating capacitor and tank inductor, both referred to as their respective values of Rp. The higher the value of these Rps, compared to the transformed antenna-ground source resistance across which they appear, the lesser the loss they cause. One approach to counter the effect the drop in Rp as frequency increases is to change to two-step inductive tuning by dividing the band into two sections as described in Article #22.

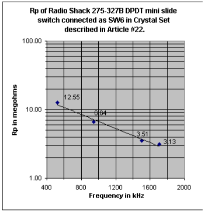
Technical Note: At any frequency, a real world capacitor of value C1 having a Q of Q1 (Q1>10), can be quite accurately modeled as a series combination of an ideal no-loss capacitor of value C1 and a resistor (Rs) equal to: (reactance of C1)/Q1. Alternatively, at any frequency, a capacitor of value C1, having a Q of Q1 (Q1>10) can be modeled as a parallel combination of an ideal capacitor of value C1 and a resistor (Rp). The resistor, Rp in this case, has a value of:: (reactance of C1)*Q1. Note that since capacitor reactance is a function of frequency, the value of the resistor will, in general, vary with frequency. In crystal radio set design it is sometimes convenient to model the tuning capacitor loss as a parallel resistor, other times as a series resistor.

Credit must go to Bill Hebbert for making the time consuming, difficult, precision measurements required for Figs. 2-5.

B2: Slide switches used in the Crystal Radio Set described in Article #22 have dielectric losses, as do all switches. To get a handle on this loss, samples of several different types of DPDT switch were measured at 1500 kHz. Each switch except the last three, below, were wired as a SPDT unit by paralleling the two sections. The Q of the capacitance appearing across the open contacts was then measured and Rp was calculated. Rp usually varies approximately inversely with frequency and therefore causes more loss at the high end of the band than at the low end. Contact resistance of all switches was found to be very low. It is unknown how well that characteristic will hold up over time. Note the extremely low loss of the Switchcraft 56206L1. The loss is so low that this switch is overkill in most crystal radio set applications. For applications in which the crystal radio set builder wants to use the lowest loss DPDT slide-switch available, this switch is the best I have found.

Table 3 - Equivalent parallel Loss Resistance (Rp) caused by the loss tangent of the dielectric of some DPDT Slide Switches at 1.5 MHz.

Brand name, model number and Size of switch	**Rp in Megohms**
ARK-LES (std. size)	2.3
Radio Shack 275-403A (std. size)	3.5
Radio Shack 275-407A (sub mini)	4.1
Stackpole S7022X (std. size)	4.9
Switchcraft 46206EE-6 (std. size)	5.1
Radio Shack 275-327B (mini)	5.7
CW (mini)	6.0
Switchcraft 46206LR (std. size)	6.5
C&K L202-1 (mini)	6.8
Switchcraft 56206L1 (mini)	13.3
Radio Shack 275-327B connected as SW3 in Article #22 (HI band)	4.1
Switchcraft 56206L1 connected as SW6 in Article #22	9.4
Radio Shack 275-327B connected as SW6 in Article #22, **See Graph--->>**	3.5



Rotary selector switches using ceramic insulation should have very low loss, even lower than the Switchcraft 56206L1. Quality switches using brown phenolic insulation probably have losses similar to slide switches using similar material. I

random uncertainty in bandwidth of around ± 1%. These random errors and quantisation errors were reduced by using the analyser's averaging of 16 measurements, to gave an overall precision (narrowness of scatter) in the measurement of Q of less than ± 1%.

The *accuracy* of the bandwidth measurements is less easy to estimate, but the errors in the AIM 4170 are probably less significant than other practical matters, such as small changes to the experimental set-up, such as the size of the coupling loop with respect to the tuned circuit. These practical aspects probably account for ±5%. In addition there is the ±1.5% error in matching the measurements (para 6.1) to the model.

So the overall measurement accuracy is assessed at ±9%, for the measurement of the overall Q and its comparison with theory. Since the capacitor resistance is about half the total this translates to an uncertainty in the capacitor resistance of ±13% (assuming the errors add in quadrature).

8. ANALYSIS OF LOSS FACTORS

8.1. Contact Resistance

There are a number of contacts contributing to the contact resistance. There is a sliding contact to the rotor, with two contacts in series, and for connection to the external circuit there is a solder tags bolted to each of the rods supporting the stator plates, and another to the static part of the sliding contact. The measurements show a combined contact resistance of 10 mΩ. The pressures on the solder tags are likely to be much greater than the slider pressure, and so their contact resistance will probably be of the order of 1 mΩ each or less, The proximity multiplier and the radiation resistance contribute a very small resistance and so uncertainties here will have a negligible effect on the results.

The major contributor is the resistance of the copper pipes, and the main uncertainties here are the resistivity and permeability of the copper, and each have an uncertainty of around ±6 %, so the uncertainty on Rwall is ±6 %. Also there was an uncertainty in the room temperature of ± 5o during the experiments, giving a further uncertainty in resistance of ±1%.

The SRF multiplier increases the resistance by only 5% and so the uncertainty here is say ±0.5% of total resistance.

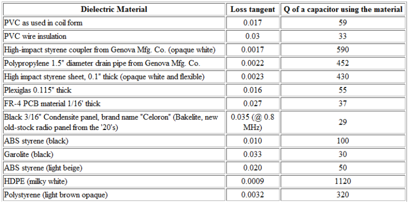
The leads to the capacitor contribute a surprisingly large 15% to the total resistance, but it is very difficult to calculate this accurately and the uncertainty to the total resistance is assumed to be ±1.5 %

These uncertainties are uncorrelated and so they can be added in quadrature, giving an overall uncertainty in the *calculations* of ±7%.

The measurements also have uncertainty and error. Measurements were of Q and carried-out on an AIM 4170 analyser. This measures Q by taking the two frequencies either side of resonance where the phase is 45o, and so the error here is related to the uncertainties in measuring frequency and phase. The analyser gives frequency to 6 places, for example 24.3652 MHz, but with a Q of say 1000, the bandwidth will be only 0.0244 MHz. Assuming the last figure is uncertain (i.e. ±0.0001) this will give an random uncertainty on the measurement of bandwidth of around ± 0.5%. The uncertainty on phase is not known, but if we assume ±1o, this will give a

would expect that the slope of the Rp vs. frequency graph of the other slide switches to be the similar that shown above.

B3: The loss tangent of an insulating material is the reciprocal of the Q of a capacitor made of that material. Some of the insulating materials listed below are used as front panels, detector stand bases, wire insulation and coil forms in crystal radio sets. A capacitor formed by the use of one of these materials, connected across a high impedance point and ground, will contribute a loss proportional to the loss tangent and capacitance.
Table 4 - Loss Tangent of some Insulating Materials
used in Crystal Radio Sets, Measured at 1.5 MHz.



Dielectric Material	Loss tangent	Q of a capacitor using the material
PVC as used in coil form	0.017	59
PVC wire insulation	0.03	33
High-impact styrene coupler from Genova Mfg. Co. (opaque white)	0.0017	590
Polypropylene 1.5" diameter drain pipe from Genova Mfg. Co.	0.0022	452
High impact styrene sheet, 0.1" thick (opaque white and flexible)	0.0023	430
Plexiglas 0.115" thick	0.016	55
FR-4 PCB material 1/16' thick	0.027	37
Black 3/16" Condensite panel, brand name "Celoron" (Bakelite, new old-stock radio panel from the '20's)	0.035 (@ 0.8 MHz)	29
ABS styrene (black)	0.010	100
Garolite (black)	0.033	30
ABS styrene (light beige)	0.020	50
HDPE (milky white)	0.0009	1120
Polystyrene (light brown opaque)	0.0032	320

Note: GE's version of polycarbonate is called Lexan. A review GE's spec. sheets of various grades of Lexan show loss tangent values at 1.0 MHz ranging between 0.006 and 0.026 . Many grades are specified 0.01.

B4: Please see Parts 10 and 11 of Article #26 as well as Table 4. Also see Table 2 of Article #22 and Article #29.

B5: Sometimes, when working with high Q tank circuits, a need pops up for a fixed capacitor with a value between say, 100 and 1000 pF that will not degrade overall circuit Q. Generic NPO disc capacitors in that range usually have a Q of around 2000-3000 at 1 MHz. Table 4 shows some caps having higher Q values. The only downside to the high Q caps is that they are SMD types and require some skill when soldering pigtail leads to them to easy connecting to one's circuit. The capacitors were measured singly, in parallel or in series, aiming for values approximating 500 pF. This was for convenience in measurement. I used solid tinned copper wire having a diameter of about 0.010" for my pig-tails. The source for the strands was a piece of stranded hook-up wire.

Table 4 - Q of easily available capacitors in the 100 - 1000 pF range

	Type	**Value in pF**	**Voltage**	**Q at about 920 kHz**	**Mfg**	**Mfg. part number**
1	Polypropylene	Two 1k in series=500	630	2,000	Xicon (Mouser)	1431-6102K
2	Polystyrene	One 470	50	6,200	Xicon (Mouser)	23PS147
3	Generic NPO disc	One 220	500	2,800	3/8" dia.	NA
4	Multilayer, hi Q SMD	Two 1k in series=500	50	8,000	Murata	ERB32Q5C1H102JDX1L
5	Multilayer, hi Q SMD	One 470	100	18,000	Murata	ERB32Q5C2A471JDX1L
6	Multilayer, hi Q SMD	Two 220 in parallel=440	200	20,000	Murata	ERB32Q5C2D221JDX1L
7	Multilayer, hi Q SMD	Two100 in parallel=200	500	40,000	Murata	ERB32Q5C2H101JDX1L

Note: Solder flux contamination on a dielectric is the enemy of high Q because it usually provides a resistive leakage path. If one gets solder flux on the insulation of a variable cap or switch, remove it with a commercial flux remover. This is important when a DX crystal radio set is involved.

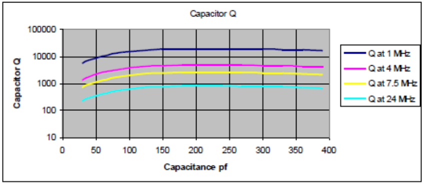
7. ACCURACY

To evaluate the likely uncertainty, it is useful to consider the individual contributions to the loss of the measurement circuit. At 10 MHz these are :

Copper Pipes (ignoring proximity and SRF) :	0.04 Ω
Proximity multiplier on above :	1.009
SRF multiplier on above :	1.048
Radiation resistance :	0.0005 Ω
Lead resistance :	0.0061 Ω



6.2. Test of Ground Effects

The measured Q was as large as 1000, and so it is possible that the floor of the room and other surfaces could be introducing loss. To evaluate this an aluminium sheet, approx 0.8mx 0.5m, was placed on the floor below the tuned circuit, a distance of about 0.8m. A measured Q of 953 was unaffected, to within the repeatability of the measurement.

6.3. Standard Capacitor

The measurement uncertainty could be reduced if a fixed capacitor could be made with a very low loss since this could be used as a standard to calibrate the system. However attempts to make such a capacitor were not successful in that it had a higher loss than the variable capacitor to be measured (see Appendix 2).

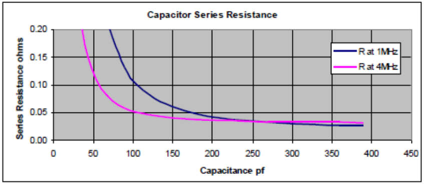
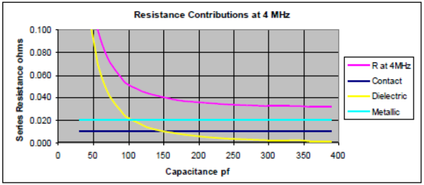
Ceramic, PZT-5H	3400	0.02			soft high sensitivity piezoelectric

Capacitors are constructed of two or more electrodes, separated by a dielectric. The dielectric is commonly ceramic, plastic film, oiled paper, mica, or air. Each one has advantages and disadvantages in regards to dielectric constant, losses,

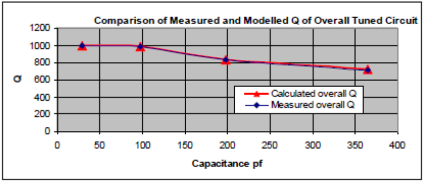


It is useful to know the contributions which each factor in Equation 6.2.1 makes to the overall resistance, and for f = 4 MHz this is shown below:



This shows that at low capacitance the dielectric loss dominates and at high capacitance the metallic loss dominates.

The capacitor Q is given by 1/ (ω C Rcap), and is given below:



The agreement is within ±1.5%.

It should be noted that the frequency is not constant in the above graph, and is 24.5 MHz at 27pf, 10.2 MHz at 198 pf, 14 MHz at 98 pf and 7.56 MHz at 365 pf, all frequencies corresponding to resonance with the inductor. These combinations of capacitance and frequency give relatively high losses, so that the overall Q to be measured is not excessive (below 1000). Also, when the capacitance is set to its minimum of 27 pf the dielectric loss is dominant, even at 24.5 MHz, and so allows the constant α to be determined fairly accurately. Similarly at 365 pf and 7.56 MHz the metallic loss and contact loss dominate permitting these to be determined.
So the series resistance of this capacitor is given by:

Rcap = 0.01+ 800 / (f C2) + 0.01(f 0.5)   6.1.2

This equation is plotted below, for f = 1 MHz and 4 MHz:

---

temperature coefficient, and, of course, cost. High dielectric constants result in smaller capacitors, but usually with poorer properties than the lower constant materials. Some properties of various dielectric materials are shown above:

The data in this table comes from many sources, not all of which are in agreement. If you have better information, want to fill in any blanks or have additional entries, please email me with the data and its source.

Low Frequency Losses

How do we specify loss? If you ask most engineers about capacitor loss, they will mumble something about "loss tangent", then disappear for an emergency coffee refill. There are several different ways of expressing capacitor losses, and this often leads to confusion. They are all very simply related, as shown below.

If you drive a perfect capacitor with a sine wave, the current will lead the voltage by exactly 90°. The capacitor gives back all the energy put into it on each cycle. In a real capacitor, the current will lead the voltage by a bit less than 90°. The capacitor will dissipate a small fraction of the energy put into it as heat. Real capacitors can be modeled, at least to a first order, as a perfect capacitor in series with a resistance. This resistance is referred to as the effective series resistance or ESR, and is only valid for a single frequency. For the examples below, assume a 0.47µF capacitor, driven at 5000 Hz, 35 volts RMS, and showing a phase angle of -89.5°. Note that the relationships shown only apply to sine waves. Capacitors can also be modeled using parallel elements, but we'll limit our discussion to the series model. You'll find a collection of "handy formulas" on this site that includes conversions between series and parallel models, plus other useful data.

Dissipation factor, or "D" as it is usually marked on test bridges, is the tangent of the difference between the phase angle of a perfect capacitor, and the capacitor in question. In our example, -90°- -89.5°=-0.5° The tangent of -0.5° is -0.00873. We take the absolute value so D=0.00873. Since this number is directly read from most test bridges, other parameters are often calculated from it. It is also known as the loss tangent and is sometimes expressed as a percentage. D=.873%

This is probably a good time to mention that by general agreement capacitive reactances are negative and inductive reactances are positive. A vector impedance meter would display the phase angle of the capacitor in question as "-89.5". Xc, the capacitive reactance would be -1/(2*pi*f*c) or -67.7255 ohms. The sign is often omitted.

Power factor, or "PF", is less common than it used to be, at least as applied to capacitors. It is the cosine of the phase angle itself. In our example, COS(-89.5)=0.00873. Note that for small angles, PF is essentially equal to D, and both are approximately equal to the phase angle expressed in radians. For large angles the situation is quite different. A power factor of 1 is 100% resistive loss whereas D can exceed 1 and approaches infinity for 100% loss.

Q is the quality factor, a dimensionless figure of merit. It is the reciprocal of D. In our example, 1/.0087=114.58, so Q=114.58.

6.1. Procedure and Initial Measurements

The Q of the total circuit was measured with an AIM 4170 network analyser. This analyser could have been connected across the variable capacitor, but the resistance of the tuned circuit at resonance is very high at this point (around 60kΩ) and the analyser is not very accurate at this level. In addition the analyser will introduce stray capacitance which will upset the measurements. The analyser was therefore connected to a 'tap', on the coil. For this the ground terminal of the analyser was connected at a point which was assumed to be at zero potential wrt ground i.e. half-way across the end pipe forming the transmission-line short. The active port of the analyser was connected to one of the copper pipes at a distance of 150 mm from the end of the pipe, and the connection lead taken down the centre of the transmission line, forming a small loop (see Photograph 2). This gave a resonant resistance at the analyser of around 700 Ω (at 14 MHz). The measurement of Q was not particularly sensitive to the exact dimensions of this coupling loop (≈ ± 5%), but the dimensions above gave the highest Q.

The measured Q was compared with the theoretical Q given by:

$$Q_{theory} = \omega L / R_s \qquad 6.1.1$$

Where L is as measured, or as given by Equation 4.4.1
Rs is given by Equation 5.1

The capacitor resistance Rc was assumed to conform to Equation 2.1, and the constants Rs, α and β were adjusted in the model to give the best correlation between the measured Q and the theoretical Q, and this was achieved with $R_s = 0.01$, $\alpha = 800$, and $\beta = 0.01$, to give the following :

Rr is the radiation resistance = 31200 (A/λ2)2
Rleads is the resistance of the leads connecting the capacitor
Rcap is series resistance of the capacitor being measured, see below.

It was assumed that the solder joints connecting the pipes together had negligible resistance, as did those connecting the metal tape to the capacitor.

Plumbing pipes were used here and the copper in these has a higher resistivity than normal copper wire, and lies between 1.92 10-8 and 2.30 10-8 Ωm (ref 6). The average of these is 2.11 10-8 and this was used here. The relative permeability μr of pure copper is unity, and it is assumed to be the same for plumbing copper.

The frequency fr was derived from the measurement of inductance as 60 MHz (para 4.3).

The capacitor was connected to the copper pipes via copper straps, having a combined length of 80 mm and a width of 11 mm and thickness 0.25 mm. The resistance of these was calculated from :

$$Rstrip = Rwall\ l / [2(w+ t)]\ Kfringing \tag{5.2}$$

where Kfringing = 1.06 +0.22 Ln w/t +0.28 (t/w)2

The fringing factor allows for the increased resistance due to the current crowding towards the edges of the strip.

6. MEASUREMENTS

Effective series resistance, or "ESR" is the value of resistance in series with a perfect capacitor that produces the phase angle error. It can be calculated by dividing D by ωC (2 pi F C). In our example, .0087/(6.28*5000*.00000047)=0.589, so ESR=0.589 ohms.

Capacitive reactance is the negative reciprocal of ωC. -1/(6.28*5000*.00000047)=-67.725, so X=-67.725 ohms.

Total impedance of a capacitor is obtained by taking the absolute value of the root sum of the squares of capacitive reactance and ESR. (67.72522+0.58922)1/2=67.727, so Z=67.727 ohms.

Capacitor current is the RMS voltage divided by the total impedance. 35/67.7=0.52 amps.

Power dissipation in the ESR component is calculated from the RMS voltage times current times the ratio of ESR to total impedance. 35*.52*(.589/67.727)=0.16 watts. Or, use I^2 times ESR. The resulting temperature rise depends on the size and heat sinking of the capacitor.

Verifying capacitor ESR on the bench requires both care and good instrumentation. Because ESR is usually small, test lead resistance and poor connections can easily contribute more resistance than the capacitor. Noise pickup from long leads or a hostile environment can make readings unstable. Note that neither D nor ESR is constant with frequency. ESR will decrease rapidly as frequency increases, then drop at a much slower rate above about 1 kHz, until it starts rising again at self resonance. Be sure to make measurements in the same frequency and voltage range that the parts will be used in- test it the way you use it. Be aware that in simulations ESR is a constant unless you take special measures to make it frequency dependent.

Dielectric Absorption is another imperfection. Briefly, the dielectric refuses to give up its full charge, and a previously discharged capacitor will self charge. This can be modeled with additional C-R pairs in parallel with the main capacitor. Dielectric absorption is a particular problem in capacitors used in integrators. There is some debate as to its importance in audio applications. Much that has been written about dielectric absorption remains obscure; at least two standard tests exist, but there is very little published data for specific parts.

Other Effects Capacitors are not 100% linear and may contribute a small amount of distortion to signals, particularly the electrolytic types. Capacitance may vary with DC voltage. Each dielectric type will have some characteristic temperature coefficient. Some capacitors are microphonic, and may also "sing" when driven at high voltages.

This relationship is useful later in determining the change of *resistance* with frequency, which Welsby gives as $1/[1-(f/fr)2]2$.

4.4. Calculated Inductance

In the initial design of the experiments it is useful to be able to calculate the approximate inductance, and the following has an accuracy of around 5% :

$$L = \mu o\ p/(2\pi)\ [\ \mathrm{Ln}\ (2p/r) + 0.25 - \mathrm{Ln}\ (p2/A)]\ SL \qquad 4.4.1$$

where p is the perimeter and A the area
SL is the inductance SRF factor $1/[1-(f/fr)2]$
$fr = 0.85(150/\ length)$

5. CALCULATED TOTAL LOSS OF RESONANT CIRCUIT

The series resistance of the resonant circuit, including the capacitor being evaluated, is given by :

$$Rs = Rwall\ [l pipes\ /\ (\pi\ dw)]\ SR\ P + Rr + Rleads + Rcap \qquad 5.1$$

where dw is the diameter of the copper pipes
$Rwall = (\rho\ \pi\ \mu o\ \mu r\ f)0.5$
ρ is the resistivity of the pipes (see below)
$\mu o = 0.4\pi\ \mu H/m$
µr is the relative permeability of the copper pipes (see below)
SR is the resistance SRF factor $=1/[1-(f/fr)2]2$
P is the proximity factor $1/\ [1- (dw/D)2]0.5$ (see Moullin ref1)
D is the spacing of the pipes (centre to centre)

4.3. Inductance changes with Frequency

The inductance of the coil changes with frequency and it was therefore measured over the frequency range of interest, and also at some lower frequencies to establish the low frequency inductance, with the following results (f is in MHz and L in μH) :

f	L	Equation 4.3.1	Error
0.5	1.1947	1.1948	0.0%
5	1.1988	1.2031	0.4%
7.459	1.2096	1.2135	0.3%
10.21	1.2464	1.2303	-1.3%
14.098	1.3147	1.2645	-3.8%
24.426	1.4322	1.4320	0.0%

It is known that the change of inductance with frequency follows approximately an equation of the form (Welsby ref 5 p37):

$$L = Lo / [1-(f/fr)2] \qquad 4.3.1$$

where Lo is the low frequency inductance
f is the frequency
fr is the Self Resonant Frequency

This equation becomes less accurate as the Self Resonant Frequency is approached, but its accuracy can be improved if a value for fr is chosen which is slightly lower than the actual SRF. A good fit with the measured inductance above is given by fr = 60 MHz (about 85% of the actual SRF), and the results of the equation with this value are shown in the table above.

Lossy Capacitors

Dr. Gary L. Johnson December 10, 2001
Manhattan,Kansas

http://www.eece.ksu.edu/~gjohnson/tcchap3.pdf

1 Dielectric Loss

Capacitors are used for a wide variety of purposes and are made of many different materials in many different styles. For purposes of discussion we will consider three broad types, that is, capacitors made for ac, dc, and pulse applications. The ac case is the most general since ac capacitors will work (or at least survive) in dc and pulse applications, where the reverse may not be true.

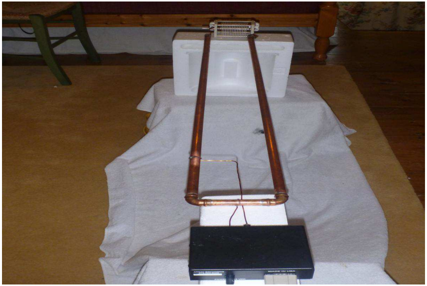
It is important to consider the losses in ac capacitors. All dielectrics (except vacuum) have two types of losses. One is a conduction loss, representing the flow of actual charge through the dielectric. The other is a dielectric loss due to movement or rotation of the atoms or molecules in an alternating electric field. Dielectric losses in water are the reason for food and drink getting hot in a microwave oven.

One way of describing dielectric losses is to consider the permittivity as a complex number,
defined as

$$\epsilon = \epsilon' - j\epsilon'' = |\epsilon| e^{-j\delta} \quad (1)$$

where
e’ = ac capacitivity
e” = dielectric loss factor

(Photograph 2). The parallel pipes and the connection strips will subsequently be referred-to as the coil.



Photograph 2 : The Measurement Apparatus

4.2. Inductance of Capacitor

The total inductance of the tuned circuit will include the inductance of the capacitor. The value for this is not known and is difficult to measure, however Field & Sinclair (ref 3) report that their measurements of capacitor inductance ‘compare well with that calculated from the dimensions of the leads, stator supports, and rotor shaft’. So for the capacitor measured here, its inductance is assumed to be represented by a rod of 7.75 mm diameter and 90 mm long, and a rod of these dimensions was inserted during the inductance measurements. Assuming the inductance of this rod is given by L = u ***l*** /2pi [ln (2 ***l*** /a) - 1] henrys, then this will have a free space inductance of 0.05 μH, about 3.5% of the total inductance.

require a large number of measurements. For instance, if there are 5 capacitance settings and each is measured at 5 frequencies this gives a total of 25 separate measurements, each having to be done with high precision. In addition more than one coil would be necessary to cover the frequency range and, for instance, Moullin used 5 coils. However, with the benefit of Equation 2.1 the task is considerably reduced, since it is now only necessary to carry-out sufficient measurements to determine the factors Rs, α and β. In this respect notice in Equation 2.1 that if C is small the dielectric loss will tend to dominate, and if C is large the metallic loss and contact resistance will tend to dominate. So measurements should be made at the minimum and maximum capacitance at the least, and also with other values for added confidence.

Only one coil was used for the measurements, and this gave resonance between 7.5 and 24 MHz with the variable capacitor. On reflection some measurements at a lower frequency may have improved the accuracy, particularly of the dielectric loss, but this would have required a second larger coil.

4. INDUCTANCE

4.1. The Coil

The inductance coil was made from two copper pipes, each 15.03 mm outside diameter and 0.985 meter long. These were spaced at 115 mm (centre to centre), and shorted at one end with a section of copper pipe.

The capacitor was connected across the open ends with two short flexible copper strips, the whole forming a tuned circuit

---

δ = dielectric loss angle

Capacitance is a complex number C∗ in this definition, becoming the expected real number C as the losses go to zero. That is, we define

$$C^* = C - jC'' \qquad (2)$$

One reason for defining a complex capacitance is that we can use the complex value in any equation derived for a real capacitance in a sinusoidal application, and get the correct phase shifts and power losses by applying the usual rules of circuit theory. This means that most of our analyses are already done, and we do not need to start over just because we now have a lossy capacitor.

Equation 1 expresses the complex permittivity in two ways, as real and imaginary or as magnitude and phase. The magnitude and phase notation is rarely used. Instead, people usually express the complex permittivity by e and tan δ,where

$$\tan\delta = \frac{\epsilon''}{\epsilon'} \qquad (3)$$

where tan δ is called either the loss tangent or the dissipation factor DF.

The real part of the permittivity is defined as

$$\epsilon' = \epsilon_r \epsilon_o \qquad (4)$$

where er is the dielectric constant and eo is the permittivity of free space.

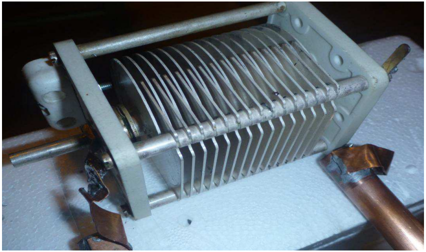
Dielectric properties of several different materials are given in Table 1 [4, 5]. Some of these materials are used for capacitors, while others may be present in oscillators or other devices where dielectric losses may affect circuit performance. The dielectric constant and the dissipation factor are given at two frequencies, 60 Hz and 1 MHz. The righthand column of Table 1 gives the approximate breakdown voltage of the material in V/mil, where 1 mil = 0.001 inch. This would be for thin layers where voids and impurities in the dielectrics are not a factor. Breakdown usually destroys a capacitor, so capacitors must be designed with a substantial safety factor.

It can be seen that most materials have dielectric constants between one and ten. One exception is barium titanate with a dielectric constant greater than 1000. It also has relatively high losses which keep it from being more widely used than it is.

We see that polyethylene, polypropylene, and polystyrene all have small dissipation factors. They also have other desirable properties and are widely used for capacitors. For high power, high voltage, and high frequency applications, such as an antenna capacitor in an AM broadcast station, the ruby mica seems to be the best.

Each of the materials in Table 1 has its own advantages and disadvantages when used in a capacitor. The ideal dielectric would have a high dielectric constant, like barium titanate, a low dissipation factor, like polystyrene, a high breakdown voltage, like mylar, a low cost, like aluminum oxide, and be easily fabricated into capacitors. It would also be perfectly stable, so the capacitance would not vary with temperature or

---



Photograph 1 : Variable Capacitor

3. MEASUREMENT PRINCIPLES

The measurement principle is that the reactance of the capacitor is tuned-out with a low loss coil, measurements are then made of the series resistance of this tuned circuit, and the calculated resistance of the coil subtracted to give that of the capacitor.

In practice the resistance values are too low to be measured accurately (≈ 0.04Ω), and so the Q (i.e. bandwidth) of the tuned circuit is measured at resonance and compared with the calculations of the Q, assuming a given loss in the capacitor. This assumed capacitor loss is then adjusted manually in the theoretical model to make the overall calculated Q agree with the measured Q.

To fully characterise the capacitor over its full capacitance range and over its useful frequency range would normally

So the measured value of Rs lay between 4.5 mΩ and 50 mΩ. The low value in this range is consistent with the value of contact resistance measured by Bock (ref 4) who gives 1 mΩ for silver plated contacts, but the high values are too large to be due to contact resistance unless the contacts were particularly dirty or worn and this seems unlikely. It is significant then that Field & Sinclair (ref 3) say that this resistance is 'joulean loss in the metal structure'. Such metallic loss will be frequency dependent due to skin effect (i.e. proportional to f-0.5), whereas contact resistance seems to be independent of frequency. So for capacitors with a long metallic path Equation 1.1 an additional term needs to be added:

$$Rcap = Rs + \alpha /(f\ C2) + \beta\ (f\ 0.5) \qquad 2.1$$

The factors Rs, α and β are assumed to be constant for any capacitor, and it is the objective here to derive them for the capacitor shown in Photograph 1 (also the capacitor shown in Annex 1). This capacitor has square ceramic ends with sides of 65mm, and an overall length of 90mm, not including the protruding shaft. Contact to the rotating shaft is at one end only, via a spring loaded washer which is stationary and makes sliding contact with a lip on the shaft. All metalwork is silver plated. The capacitor has a range of 25 – 390 pf.

voltage. No such dielectric has been discovered so we must apply engineering judgment in each situation, and select the capacitor type that will meet all the requirements and at least cost.

Capacitors used for ac must be unpolarized so they can handle full voltage reversals. They also need to have a lower dissipation factor than capacitors used as dc filter capacitors, for example. One important application of ac capacitors is in tuning electronic equipment. These capacitors must have high stability with time and temperature, so the tuned frequency does not drift beyond some specified amount.

Another category of ac capacitor is the motor run or power factor correcting capacitor. These are used on motors and other devices operating at 60 Hz and at voltages up to 480 V or more. They are usually much larger than capacitors used for tuning electronic circuits, and are not sold by electronics supply houses. One has to ask for motor run capacitors at an electrical supply house like Graingers. These also work nicely as dc filter capacitors if voltages higher than allowed by conventional dc filter capacitors are required.

The term power factor PF may also be defined for ac capacitors. It is given by the expression

$$\mathrm{PF} = \cos\theta \qquad (5)$$

where θ is the angle between the current flowing through the capacitor and the voltage across it.
The capacitive reactance for the sinusoidal case can be defined as

$$X_C = \frac{1}{\omega C} \quad (6)$$

where ω =2 πf rad/sec, and f is in Hz.

In a lossless capacitor, e"= 0, and the current leads the voltage by exactly 90o. If e" is greater than zero, then the current has a component in phase with the voltage.

$$\cos\theta = \frac{\epsilon''}{\sqrt{(\epsilon'')^2 + (\epsilon')^2}} \quad (7)$$

For a good dielectric, e'>>e", so

$$\cos\theta \approx \frac{\epsilon''}{\epsilon'} = \tan\delta \quad (8)$$

Therefore, the term power factor is often used interchangeably with the terms loss tangent or dissipation factor, even though they are only approximately equal to each other.

We can define the apparent power flow into a parallel plate capacitor as

$$S = VI = \frac{V^2}{-jX_C} = jV^2\omega C^* = jV^2\frac{\omega A}{d}(\epsilon' - j\epsilon'') = V^2\frac{\omega A}{d}\epsilon_r\epsilon_o(j + \mathrm{DF})$$

(9)

By analogy, the apparent power flow into any arbitrary capacitor is

that proximity effect was minimal, and shorted at the far end. It therefore resembled a shorted two-wire transmission line, and the capacitor to be measured was connected to the open ends. This type of inductor is used here and is shown in Photograph 2.

A number of authors have measured the loss of variable capacitors (refs 1, 2, 3), and found that the series resistance conformed to the following equation :

Rcap = Rs + α /(f C2) ohms 1.1

where f is the frequency
C is the capacitance

The first factor Rs is a constant resistance, often accredited to the contact resistance of the slip rings, or equivalent. The second factor is due to the loss in the insulators, where again factor α is a constant. Jackson (ref 2) summarises his own measurements and those of previous workers as follows :

Rcap = 0.0045 + 0.028 [106/(f C2)] ohms (Jackson) 1.2
Rcap= 0.05 + 0.091 [105/(f C2)] ohms (Moullin) 1.3
Rcap= 0.007 + 0.012[105/(f C2)] +10/(f 2C2) ohms (Dye) 1.4
Rcap= 0.02 + 0.022 [103/(f C2)] ohms (Wilmotte) 1.5

where f is in MHZ and C in pf

Notice that Dye has an additional term related to a constant resistance across the dielectric, but this term is only significant at very low frequencies, and so is not considered here.

2. EVALUATION OF LOSS COMPONENTS

Measuring the Loss in Variable Air Capacitors

Alan Payne 2013

http://g3rbj.co.uk/wp-content/uploads/2013/10/Measurements_of_Loss_in_Variable_Capacitors_issue_2.pdf

The resistive loss of variable air capacitors is difficult to measure because they have a very high Q. The method described here uses a twin-wire transmission line made from copper pipe as the inductor to tune-out the reactance of the capacitor.

Previous authors have shown that the capacitor loss comes partly from resistive loss and partly from dielectric loss in the insulating supports. They have attributed the resistive loss to that in the rotating contacts, but it is shown that there is also a major contribution from the metallic part of the structure, although the plates themselves have negligible resistance.

1. INTRODUCTION

The loss resistance of high quality variable capacitors is difficult to measure because of the presence of the very high reactance. This must be tuned-out with an inductor, which must be of very high Q if its resistance is not to dominate the measurements, and its own resistance must be calculable to a high degree of accuracy, because this cannot be independently measured. Conventional helical coils cannot be used therefore because they do not have a sufficiently high Q, and, more importantly their loss resistance cannot be calculated with sufficient accuracy. Moullin (ref 1) solved this problem by making his inductor from two parallel conductors, spaced so

The power dissipated in the capacitor is

$$P = V^2\omega C'' = V^2\omega C(\mathrm{DF}) \quad (11)$$

Example

Find the real and reactive power into a ruby mica capacitor with area A = 0.03m2, and a dielectric thickness d = 0.001 m, if the voltage is 2000 V (rms) at a frequency f = 1 MHz.

$$S = V^2 \frac{\omega A}{d} \epsilon_r \epsilon_o (j + \mathrm{DF})$$

$$= (2000)^2 \frac{2\pi(10^6)(0.03)}{0.001}(5.4)(8.854 \times 10^{-12})(j + 0.0003)$$

$$= j36040 + 10.8$$

The capacitor is absorbing 36040 capacitive VARs (Volt Amperes Reactive) and 10.8 Watts. The real power of 10.8 W appears as heat and must be removed by appropriate heat sinks.

The real power dissipation in a capacitor varies directly with frequency if the dissipation factor remains constant, and also with the square of the voltage. At low frequencies, the voltage limit is determined by the dielectric strength. At high frequencies, however, the voltage limit may be determined by the ability of the capacitor to dissipate heat. If the ruby mica capacitor in the previous example could safely dissipate only 10 W, but was to be used at 5 MHz, the operating voltage must be reduced from 2000 V to keep the losses in an acceptable range.

The dissipation factor varies significantly with frequency for some materials in Table 1. The actual variation must be determined experimentally. If interpolation or extrapolation seems necessary to find the loss at some frequency not given in

---

Test System Safety

Many electrical test systems or instruments are capable of measuring or sourcing hazardous voltage and power levels. It is also possible, under single fault conditions (e.g., a programming error or an instrument failure), to output hazardous levels, even when the system indicates no hazard is present. These high-voltage and power levels make it essential to protect operators from any of these hazards at all times. It is the responsibility of the test system designers, integrators and installers to make sure operator and maintenance personnel protection is in place and effective. Protection methods include:

* Design test fixtures to prevent operator contact with any hazardous circuit.
* Make sure the device under test is fully enclosed to protect the operator from any flying debris.
* Double insulate all electrical connections that an operator could touch. Double insulation ensures the operator is still protected, even if one insulation layer fails.
* Use high-reliability, fail-safe interlock switches to disconnect power sources when a test fixture cover is opened.
* Where possible, use automated handlers so operators do not require access to the inside of the test fixture.
* Provide proper training to all users of the system so they understand all potential hazards and know how to protect themselves from injury.

Dale Cigoy is lead applications engineer at Keithley Instruments (keithley.com).

suitable soak period. After the capacitors have been tested, the voltage source should be set to zero, and then some time allowed so the capacitors can discharge before they are removed from the test fixture.

Note that in Figure 4 the capacitors have a discharge path through the normally closed contacts of the relays. To prevent electric shock, test connections must be configured in such a way that the user cannot come in contact with the conductors, connections or DUT. Safe installation requires proper shielding, barriers and grounding to prevent contact with conductors.

More complex test systems that combine leakage measurement with capacitance measurements, dielectric absorption and other tests, if desired, are possible. A simplified schematic of such a test system using an LCZ bridge and a picoammeter with a voltage source is shown in Figure 5.

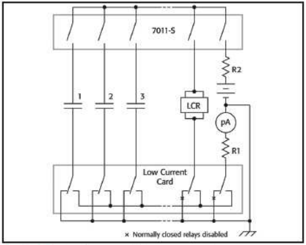

FIGURE 5. Capacitance and IR measurement system.

the Table, the best assumption would be that DF varies linearly with log f. That is, if DF = 0.02 at f = 102 and 0.01 at f = 106, a reasonable assumption at f = 104 would be that DF = 0.015.

The basic circuit model for a capacitor is shown in Fig. 1. Any conductor, whether straight or wound in a coil, has inductance, and the capacitor inductance is represented by a series inductance Ls. The effects of conductor resistance and dielectric losses are represented by a series resistance Rs. Leakage current through the capacitor at dc flows through a parallel resistance Rp. In some manufacturer's databooks, these are called ESL, ESR, and EPR, where

Ls = ESL = equivalent series inductance
Rs = ESR = equivalent series resistance
Rp = EPR = equivalent parallel resistance

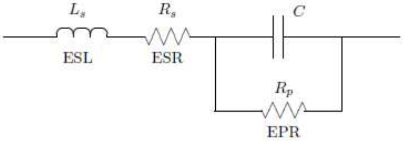

Figure 1: Equivalent Circuit for a Capacitor

This circuit indicates that every capacitor has a self-resonant frequency, above which it becomes an inductor. This is certain to puzzle a student making measurements on a capacitor above this frequency if the student is not aware of this fact. Rs is readily measured by applying this frequency to a capacitor, measuring the voltage and current, and calculating the ratio. The capacitive and inductive reactances cancel at the resonant frequency, leaving only Rs to limit the current. The resistance

Rp will always be much larger than the capacitive reactance at the resonant frequency, so this resistance can be neglected for this computation.

The self-resonant frequency of a high capacitance unit is lower than that for a low capacitance unit. Hence, in some circuits we will see two capacitors in parallel, say a 10μF in parallel with a 0.001μF capacitor as shown in Fig. 2. At first glance, this seems totally unnecessary. However, the larger capacitor is used to filter low frequencies, say in the audio range, while the small capacitor filters the high frequencies which are above the self-resonant frequency of the large capacitor.

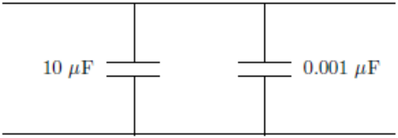

Figure 2: Capacitors in Parallel to Filter Two Different Frequencies

An example of the variation of Rs and self-resonant frequency fres with capacitance value and rated voltage is given in Table 2. These are metallized polypropylene capacitors designed for switch-mode power supplies by the company Electronic Concepts, Inc. This application requires a low Rs and a high fres so capacitors designed for other applications will tend to have higher values of Rs and lower values of fres.

---

that can integrate easily with a switching system capable of higher channel counts.

Configuration examples.

Producing enough useful data for statistical analysis requires testing a large quantity of capacitors quickly. Obviously, performing these tests manually is impractical, so an automated test system is required. Figure 4 illustrates such a system, which employs an electrometer with built-in voltage source, as well as a switching mainframe that houses a low current scanner card and a Form C switching card. In this test setup, a single instrument provides both the voltage sourcing and low current measurement functions. A computer controls the instruments to perform the tests automatically.

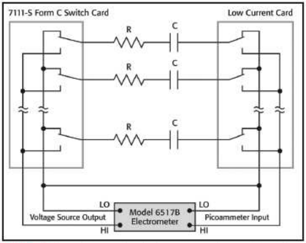

FIGURE 4. Example capacitor leakage test system configuration.

One set of switches is used to apply the test voltage to each capacitor in turn; a second set of switches connects each capacitor to the electrometer's picoammeter input after a

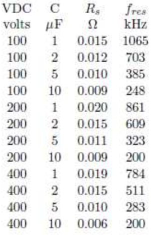
Test Hardware Considerations

A variety of considerations go into the selection of the instrumentation used when measuring capacitor leakage:

- Although it is certainly possible to set up a system with a separate voltage source, an integrated one simplifies the configuration and programming process significantly, so look for an electrometer or picoammeter with a built-in variable voltage source. A continuously variable voltage source calculates voltage coefficients easily. For making high-resistance measurements on capacitors with high voltage ratings, consider a 1000 V source with built-in current limiting. For a given capacitor, a larger applied voltage within the voltage rating of the capacitor will produce a larger leakage current. Measuring a larger current with the same intrinsic noise floor produces a greater signal-to-noise ratio and, therefore, a more accurate reading.
- Temperature and humidity can have a significant effect on high-resistance measurements, so monitoring, regulating and recording these conditions can be critical to ensuring measurement accuracy. Some electrometers monitor temperature and humidity simultaneously. This provides a record of conditions, and permits easier determination of temperature coefficients. Automatic time-stamping of readings provides a further record for time-resolved measurements.
- Incorporating switching hardware into the test setup allows automating the testing process. For small batch testing in a lab with a benchtop test setup, consider an electrometer that offers the convenience of a plug-in switching card. For testing larger batches of capacitors, look for an instrument

The operating frequency range will obviously be less than the self-resonant frequency. This could easily be as low as a few kHz for large motor run capacitors.

Table 2: Capacitor Resistance and Self-resonant Frequency for Electronic Concepts Type 5MP Metallized Polypropylene capacitors.



VDC volts	C μF	R_s Ω	f_{res} kHz
100	1	0.015	1065
100	2	0.012	703
100	5	0.010	385

400	2	0.015	511
400	5	0.010	283
400	10	0.006	200

Capacitors will always be rated for a working voltage as well as a specific value of capacitance. This voltage will always be well under the breakdown voltage of the dielectric. It may be specified either as a dc voltage or an ac voltage, depending on the application. Motor run capacitors are always operated on ac, so the voltage is specified as, say, 370 or 480 VAC. They can also be operated on dc, with a dc rating of at least √2 times the ac rating. Electrolytic capacitors that can only be operated on dc will have their working voltage expressed as WVDC. This is the maximum dc voltage, plus the peak of the ac ripple voltage, that should be continuously applied to a capacitor to prevent excessive deterioration and aging. Capacitors that are sometimes used on ac, and sometimes on dc, usually have working voltages expressed as WVDC, as was the case for the polypropylene capacitors in Table 2.

We will now present some more detailed background information on several of the dielectrics shown in Table 1.

Mica is a natural material that can be easily split into thin layers. It is very stable and does not deteriorate with age. The maximum capacitance is on the order of 0.03 μF. Mica capacitors tend to be quite expensive and the larger sizes are used only in critical applications like radio transmitters.

Glass capacitors were first developed during World War II as a replacement for mica capacitors when supplies of mica were threatened. Glass capacitors exhibit excellent long-term parametric stability, low losses, and can be used at high frequencies. They are used in aerospace applications where capacitance must not vary. The maximum size is limited to about 0.01μF

Paper capacitors use kraft paper impregnated with non-ionized liquid electrolyte as the dielectric between aluminum foils. These capacitors can provide large capacitances and voltage ratings but tend to be physically large. The thickness of the paper layers and the particular electrolyte used can be varied to produce a wide range of electrical characteristics, which is the reason for not listing paper in the dielectrics of Table 1.

Ceramic capacitors are made with one of a large number of ceramic materials, which include aluminum oxide, barium titanate, and porcelain. These are very widely used as bypass capacitors in electronic circuits. The older style is a single

The series resistor also adds Johnson noise – the thermal noise created by any resistor – to the measurement. At room temperature, this is roughly 6.5×1010 amps, p-p. The current noise in a 1 TΩ feedback resistor at a typical 3 Hz bandwidth would be ~8×10-16 A. When measuring an insulation resistance of 1016Ω at 10 V, the noise current will be 80% of the measured current.

Alternate test circuit.

Greater measurement accuracy can be achieved by including a forward-biased diode (D) in the circuit (Figure 3). The diode acts like a variable resistance, low when the charging current to the capacitor is high, then increases in value as the current decreases with time. This allows the series resistor used to be much smaller because it is only needed to prevent overload of the voltage source and damage to the diode if the capacitor is short-circuited. The diode used should be a small signal diode, such as a 1N914 or a 1N3595, but it must be housed in a light-tight enclosure to eliminate photoelectric and electrostatic interference. For dual-polarity tests, two diodes should be used back to back in parallel.

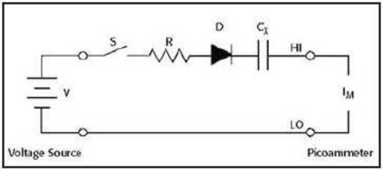

FIGURE 3. Alternative test circuit that incorporates a small-signal diode.

1MΩ·µF to 100 MΩ·µF. For example, a 4.7 µF aluminum cap specified as 50 MΩ·µF is guaranteed to have at least 10.6 MΩ insulation resistance.

Capacitor leakage test method.

Figure 2 illustrates a general circuit for testing capacitor leakage. Here, the voltage is placed across the capacitor (CX) for the soak period; then the ammeter measures the current after this period has elapsed. The resistor (R), which is in series with the capacitor, serves two important functions. First, it limits the current, in case the capacitor becomes shorted. Second, the decreasing reactance of the capacitor with increasing frequency will increase the gain of the feedback ammeter. The resistor limits this increase in gain to a finite value. A reasonable value is one that results in an RC product from 0.5 to 2 sec. The switch (S), while not strictly necessary, is included in the circuit to allow control over the voltage to be applied to the capacitor.

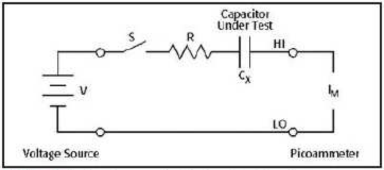

FIGURE 2. A simple capacitor leakage test circuit.

layer of dielectric separating two conducting plates and packaged in a small disc. The newer style is the monolithic, which appears in a rectangular package. It consists of alternating layers of ceramic material and printed electrodes which are sintered together to form the final package. The self resonant frequency is on the order of 15 MHz for the 0.01µF size, for a total lead length of 0.5 inch, and on the order of 165 MHz for the 0.0001µF = 100 pF size. Ceramic capacitors are classified into Class 1 (r<600) and Class 2 (r>600) by the Electronics Industries Association (EIA). Class 1 ceramic capacitors tend to be larger than their Class 2 counterparts, and have better stability of values with changes in temperature, voltage, or frequency. The best Class 1 capacitor, with nearly constant characteristic, will be labeled 'C0G' using EIA designators, but is often referred to as 'NP0' which stands for 'negative-positive-zero' (temperature coefficient).

Plastic-film capacitors use extremely thin sheets of plastic film as the dielectric between capacitor plates, usually in a coil construction. They have low losses and good resistance to humidity. Four common materials are:
1. Polycarbonate
2. Polypropylene
3. Polystyrene
4. Teflon

Generally speaking, as one moves down in this list from polycarbonate to Teflon, the capacitors get larger, better, and more expensive.

Historically, low-budget Tesla coilers have used either saltwater capacitors (as Tesla himself did) or homemade rolled polyethylene and foil capacitors. The saltwater capacitors are lossy and heavy. They are one of the first components to be replaced as a new coiler grows with his hobby. The homemade foil capacitors are limited by corona onset to about 7000 V. They are oil filled, so if the container leaks or is tipped over, one has a real mess. Serious coilers would look for commercial high voltage, high current, pulse rated capacitors made by specialty companies like Maxwell. These worked fine, but were expensive if purchased new, and difficult to find on the used market.

This all changed in 1999 when the Tesla coil community moved en masse to multi mini capacitors (MMC). These are small commercial capacitors that one buys by the sackful from Digi-Key and connects in series and parallel strings to get the required ratings.

There are several different capacitor series, some of which are more suitable for Tesla coil work than others. One should look for capacitor types that are rated for “high voltage, high frequency, and high pulses”. A dissipation factor of 0.1% at 1 kHz is good, as is polypropylene for the dielectric. The ECWH(V) and ECQP(U) series of capacitors are good. The Panasonic ECQ-E capacitors utilize metallized polyester (Mylar) which has a higher dissipation factor (1% at 1 kHz) than the polypropylene capacitors.

Capacitor ratings have received a great deal of attention by Tesla coilers. A given capacitor might be rated at 1600 VDC and 500 VAC. The AC rating is always for rms values, so the peak voltage would be about 700 V for a rating of 500 VAC. A capacitor in a Tesla coil primary experiences full voltage reversal, so it would seem wise to find the AC rating, multiply by √2, and divide that into the peak voltage available from the iron core transformer to find the number of series capacitors to use.

source and the capacitance. This is especially true for capacitance values >1 nF. A typical series resistor would be 10 kΩ to 1 MΩ.

Capacitor Leakage

Leakage is one of the less-than-ideal properties of a capacitor, expressed in terms of its insulation resistance (IR). For a given dielectric material, the effective parallel resistance is inversely proportional to the capacitance. This is because the resistance is proportional to the thickness of the dielectric, and inverse to the capacitive area. The capacitance is proportional to the area and inverse to the separation. Therefore, a common unit for quantifying capacitor leakage is the product of its capacitance and its leakage resistance, usually expressed in megohms-microfarads (MΩ·µF). Capacitor leakage is measured by applying a fixed voltage to the capacitor under test and measuring the resulting current. The leakage current will decay exponentially with time, so it’s usually necessary to apply the voltage for a known period (the soak time) before measuring the current.

In theory, a capacitor’s dielectric could be made of any non-conductive substance. However, for practical applications, specific materials are used that best suit the capacitor’s function. The insulation resistance of polymer dielectrics, such as polystyrene, polycarbonate or Teflon, can range from 104 MΩ·µF to 108 MΩ·µF, depending on the specific materials used and their purity. For example, a 1000 pF Teflon cap with an insulation resistance higher than 1017 Ω is specified as >108 MΩ·µF. The insulation resistance of ceramics such as X7R or NPO can be anywhere from 103 MΩ·µF to 106 MΩ·µF. Electrolytic capacitors such as tantalum or aluminum have much lower leakage resistances, typically ranging from

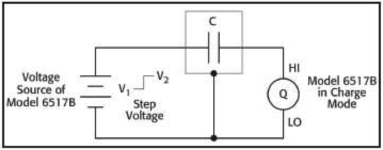

FIGURE 1. Capacitance measurement using an electrometer with an integrated voltage source.

Then, the voltage source should be turned on and the charge reading noted immediately. The capacitance can then be calculated from:

$$C = \frac{Q_2 - Q_1}{V_2 - V_1}$$

where

Q2 = final charge
Q1 = initial charge (assumed to be zero)
V2 = step voltage
V1 = initial voltage (assumed to be zero)

After the reading has been recorded, reset the voltage source to 0 V to dissipate the charge from the device. Before handling the device, verify the capacitance has been discharged to a safe level. The unknown capacitance should be in a shielded test fixture. The shield is connected to the LO input terminal of the electrometer. The HI input terminal should be connected to the highest impedance terminal of the unknown capacitance. If the rate of charge is too great, the resulting measurement will be in error because the input stage becomes temporarily saturated. To limit the rate of charge transfer at the input of the electrometer, add a resistor in series between the voltage

Experience of coilers, however, has been that there are sufficient safety factors built into the capacitors that using the DC rating is quite acceptable. For example, a 15 kV transformer has a peak voltage of 15√2 = 21. 2 kV. Divide 21.2 by 1.6 for 1600 VDC capacitors to get 13.25. Use either 13 or 14 capacitors in series.

The voltage rating is not determined by the dielectric breakdown voltage as much as it is by the Ionization or Corona Inception Level . This refers to the level at which ionization or partial discharges can begin to occur inside a bubble of entrapped air or within an air-filled void within the solid dielectric system. If one had perfect dielectrics and could always exclude any entrapped air, derating for this phenomenon would not be necessary. Corona inside a capacitor will chemically degrade the dielectric material over a period of time until the capacitor ultimately fails. Manufacturers of capacitors might select a voltage rating whereby their capacitors will last for one million hours before this occurs. In Tesla coil use, 100 hours of actual operation is a long time. This helps explain why coilers can exceed the manufacturer ratings without immediate problems.

There is evidence that operating a capacitor above its ac voltage rating will shorten its life by a factor of the overvoltage ratio raised to the 15th power. Suppose we have a capacitor rated at one million hours at 500 VAC. For economic reasons we are thinking about operating it at 700 VAC. The life reduction factor is (700/500)15 = 155. 57. Dividing one million by 155.57 gives an expected life of 6428 hours or almost one year of continuous operation. This is more than adequate for most Tesla coil applications.

One brand of capacitor is the WIMA. Terry Fritz comments about them: "The switching power supplies we build have WIMAs in pulsed duty similar to that seen in Tesla coil use.

The real indicator of how long they live is how warm they get. If they heat to about 5 degrees C above the ambient, then they last forever. At about 8 degrees above ambient, we see occasional failures. At 10 degrees, they get to be a problem. In many situations, we go beyond the WIMA chart derating in pulsed applications with no problem at all, just being sure they don't get hot."

WIMA experts say that partial discharges occur only above a certain voltage level and only on ac. Frequency does not seem to be a factor. They agree that the ac rating can be exceeded in Tesla coil applications, but without a serious investigation, were mentioning factors like 1.25 to 1.5.

Some capacitors that are candidates for a MMC use actual metal foil for electrodes while others use metallized plastic. The metal foil devices are physically larger for a given rating and are much more robust in Tesla coil service.

Dielectric material, electrode thickness, and lead size all limit the rate at which charge can be added to or removed from a capacitor. This limit is expressed as the dV/dt limit. The peak current I peak can be determined from the dV/dt value by the equation

$$I_{peak} = \frac{dV}{dt}C \qquad (12)$$

The coulomb's function of an electrometer can be used with a step voltage source to measure capacitance levels ranging from <10pF to hundreds of nanofarads.

The unknown capacitance is connected in series with the electrometer input and the step voltage source.

The calculation of the capacitance is based on this equation:

$$C = \frac{Q}{V}$$

Figure 1 illustrates a basic configuration for measuring capacitance with an electrometer with an internal voltage source. The instrument is used in the charge (or coulombs) mode, and its voltage source provides the step voltage. Just before the voltage source is turned on, the meter's zero check function should be disabled and the charge reading suppressed by using the REL function to zero the display. (The purpose of zero check is to protect the input FET from overload and to zero the instrument. When zero check is enabled, the input of the electrometer is a resistance from roughly 10 MΩ to 100 MΩ, depending on the electrometer used. Zero check should be enabled when changing conditions on the input circuit, such as changing functions and connections. The REL function subtracts a reference value from actual readings. When REL is enabled, the instrument uses the present reading as a relative value. Subsequent readings will be the difference between the actual input value and the relative value.)

Capacitor Testing Challenges and Solutions

by Dale Cigoy

http://www.circuitsassembly.com/cms/component/content/article/159/10164-capacitor-testing-challenges-and-solutions

Chip caps are prone to leakage, so consider these test methods for minimizing electrical failures.

Capacitors are widely used for bypassing, coupling, filtering and tunneling electronic circuits. However, to be useful, their capacitance value, voltage rating, temperature coefficient and leakage resistance must be characterized. Although capacitor manufacturers perform these tests, many electronics assemblers also perform some of these tests as quality checks. This article looks at some of the challenges associated with capacitor testing, as well as some of the test techniques used.

A capacitor is somewhat like a battery in that they both store electrical energy. Inside a battery, chemical reactions produce electrons on one terminal and store electrons on the other. However, a capacitor is much simpler than a battery because it can't produce new electrons – it only stores them. Inside the capacitor, the terminals connect to two metal plates separated by a non-conducting substance known as a dielectric.

A capacitor's storage potential, or capacitance, is measured in farads. A one-farad (1 F) capacitor can store one coulomb (1 C) of charge at one volt (1 V). A coulomb is 6.25´1018 electronics. One amp represents a rate of electron flow of 1C of electrons per second, so a 1 F capacitor can hold one amp-second (1 A/s) of electrons at 1 V.

---

where appropriate multipliers should be used to get everything in volts, seconds, and farads. By way of reference, a 1000 pF capacitor rated for 10,000 V/µs will withstand 10 A surges. A capacitor with a dV/dt rating less than 1000 V per 5µs probably does not have metal foil endplates and should not be used.

The peak current that a Tesla coil primary capacitor must provide is determined by the capacitor voltage and the surge impedance. If the secondary were removed, the surge impedance would be

$$Z_s = \sqrt{\frac{L_1}{C_1}} \qquad (13)$$

where C1 is the capacitance in the Tesla coil primary and L1 is the inductance of the primary. When the secondary is in place, the surge impedance will increase from the above value, so the peak current required from the capacitor will be less. Using the above expression for Zs should be a worst case calculation. If it tells you that there might be 100 A flowing after the gap shorts, and your individual capacitors are rated at 10 A each, then you would need ten parallel strings. Since this figure includes some factor of safety, you might be able to get by with somewhat fewer strings. One WIMA expert said that the maximum amperage rating is not as critical as the Corona Inception Level mentioned above.

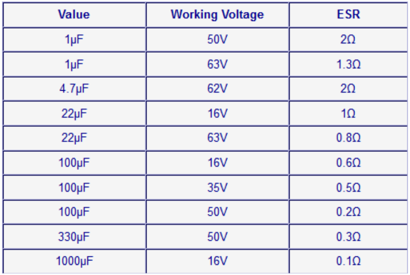
The polypropylene capacitors useful for Tesla coil work have a self-healing mode. A partial discharge will eventually cause a local failure. A burst of energy through this short will vaporize everything around the short, effectively removing the short.

The capacitor continues to operate, but with a slightly lower capacitance due to some of the electrodes being removed. It is a good idea to carefully measure the capacitance of the MMC periodically. A decrease of even 1% could indicate that the capacitors are being stressed, and that total failure is possible.

Terry Fritz reports testing some WIMA MKS 4 (K4) capacitors rated at 1μF and 400VDC on a large DC supply. These are metallized polypropylene dielectric capacitors that are encapsulated in epoxy filled 3×1 cm rectangles. Starting at about 900 V there are a few little snaps, indicating that the dielectric had punched through and the arc blasted the thin metal layer on the other side. Going to 1200 V gave a few more snaps. Around 1500 V there were many snaps and the capacitor shorted out.

When a capacitor cleanly blows apart, that is a sign that they were destroyed by over voltage. When a capacitor puffs up and looks melted and burned, that is from too much current. It is always a good idea to think about possible failure modes, and put the capacitors in appropriate enclosures to protect bystanders.

I had a student build a small design project once, that illustrates this point. He used an electrolytic capacitor rated at about 25 VDC in some circuit for 120 VAC usage, and I did not notice it before testing. He was proudly demonstrating performance, using a variac to bring up the voltage. At about 90 V, the electrolytic capacitor exploded with a noise somewhere between a pistol and a small shotgun. The contents of the capacitor, about a cubic centimeter of plastic fibers, hit the student in the middle of the chest. He was not injured, but for a brief moment he thought he had been killed by this exploding capacitor. I suspect he still pays



Value	Working Voltage	ESR
1µF	50V	2Ω
1µF	63V	1.3Ω
4.7µF	62V	2Ω
22µF	16V	1Ω
22µF	63V	0.8Ω
100µF	16V	0.6Ω
100µF	35V	0.5Ω
100µF	50V	0.2Ω
330µF	50V	0.3Ω
1000µF	16V	0.1Ω

Conclusion

All the capacitors had an ESR of 2 ohms or less and most of the values that you would use in a power supply (22µF and up) had an ESR of less than 1 ohm. As a rule of thumb, higher valued capacitors with higher working voltages had a lower ESR, although there were some exceptions so this cannot be guaranteed.

Keep in mind that the ESR for standard electrolytic capacitors increases with lower temperatures. For example, it will typically increase by 20 to 30 times when the temperature drops from 25°C to -40°C.

---

more attention to capacitor voltage ratings than most people.

Many coilers recommend placing resistors across the MMC to bleed off the charge after power is removed. This can eliminate some very unpleasant surprises when making adjustments between runs. One can get true high voltage resistors but they are expensive. Most use a long chain of ordinary resistors therefore. Digi-Key sells 0.5 W carbon film resistors rated at 350 volts each for about two cents each in quantity. At this price, there is little point in not using adequate safety factors. Suppose we feel comfortable in operating a 0.5 W resistor at 0.1 W and at the rated peak voltage of 350 V each. We solve for the resistance as

$$R = \frac{V^2}{P} = \frac{(350/\sqrt{2})^2}{0.1} = 612\ \ \text{k}\Omega$$

where we round off to the nearest standard value of 620 kΩ.

The number of resistors needed for a string across say a 15 kV transformer secondary would be

$$N = \frac{15000\sqrt{2}}{350} = 60\ \ \text{resistors}$$

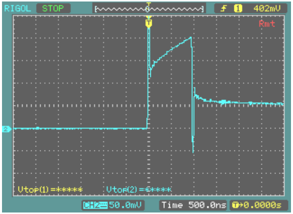
We then check the time constant to get a measure of how long it takes to discharge a

Table 3: Dielectric Constant r and Dissipation Factor DF of Water.

		Frequency in Hz			
Temperature		10^5	10^6	10^7	10^{10}
1.5°C	ϵ'_r	87.0	87.0	87	38
	DF	0.1897	0.01897	0.00195	1.026
25^o	ϵ'_r	78.2	78.2	78.2	55
	DF	0.3964	0.03964	0.00460	0.545
85°C	ϵ'_r	58	58	58	54
	DF	1.2413	0.12413	0.01259	0.259

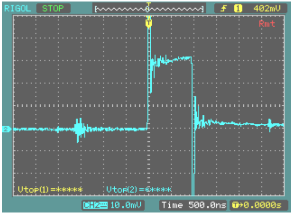
capacitor chain. If the capacitance happened to be 27 nF, the time constant would be
$\tau = RC = (60)(620000)(27\times10{-}9) = 1$ second

A capacitor will be mostly discharged after five time constants or 5 seconds in this example. There are obviously many other design possibilities. If we assumed the resistors would accept a higher voltage before arcing over, then we would want to use higher ohm values to keep heating within bounds. Terry Fritz tested some Yageo 10 MΩ 0.5 W carbon film resistors to see where they would actually fail. At 4000 V the resistor started to turn brown and smoke a little. This should be expected since it is now drawing 2 W, four times its power rating. At 5300 V, it gave a very satisfying crack and arced along its outside surface. After that, the 2 MΩ resistor measured 11.1 MΩ. So a resistor specified at 350 V actually failed at 5300 V, a safety factor of 15. Terry sees no problem with using these 0.5 W resistors up to 1000 V if the resulting wattage is not excessive.



Results

The following table lists the results for a representative collection of aluminium electrolytic capacitors in my parts collection. The manufacturers were Elete and Lelon and they were bought from Futurlec and Jaycar (in Australia). They represent the typical components that a hobbyist would have access to.



This method will work for values of ESR from 0.1Ω to greater than 10Ω. Alas, it is not very accurate - but then the ESR of a capacitor is not a precise value anyway and I was only looking for an approximation.

The main problem with this technique is that it is not very effective with capacitors below 10µF. With these small values the charge on the capacitor will rapidly rise making it difficult to estimate the height of the pulse before the effect of charging takes over – although, with some guesswork it can be still used for values down to 1 µF.

This is illustrated in the screenshot on the left. The capacitor on test was a 2.2µF 63VW electrolytic and it is possible to estimate that the start of the pulse is about 130mV (vertical scale is 50mV/division). This gives an ESR of 1.3Ω.

Equivalent Series Resistance (ESR) of Capacitors

QuadTech, Incorporated
http://www.lowesr.com/QT_LowESR.pdf

Questions continually arise concerning the correct definition of the ESR (Equivalent Series Resistance) of a capacitor and, more particularly, the difference between ESR and the actual physical series resistance (which we'll call Ras), the ohmic resistance of the leads and plates or foils. The definition and application of the term ESR has often been misconstrued. We hope this note will answer any questions and clarify any confusion that might exist. Very briefly, ESR is a measure of the total lossiness of a capacitor. It is larger than Ras because the actual series resistance is only one source of the total loss (usually a small part).

The Series Equivalent Circuit

At one frequency, a measurement of complex impedance gives two numbers, the real part and the imaginary part: Z = Rs + jXs. At that frequency, the impedance behaves like a series combination of an ideal resistance Rs and an ideal reactance Xs (Figure 1).

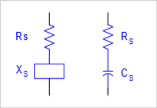


Figure 1: Equivalent Series Circuit Representation

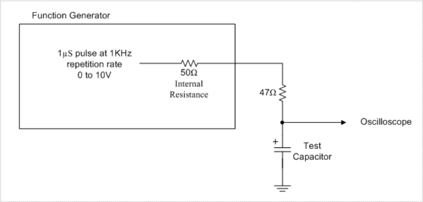
If Xs is negative, the impedance is capacitive and the general reactance can be replaced with a capacitance of:

Test Setup

The method that I used is quite simple and is shown in the diagram below.



I used a function generator to generate narrow pulses (1µS wide) with a slow repetition rate (1KHz). This drove a voltage divider with the test capacitor in the bottom leg and 100Ω in the top leg. Because of the narrow pulse, the capacitor did not have enough time to build up a charge, so the voltage across it represented the voltage drop caused by its ESR.

With the voltage of each pulse set at 10V this arrangement meant that the height of the pulse (in mV) across the test capacitor divided by 100 was equivalent to the capacitor's ESR in ohms. For example, a pulse height of 80mV represented an ESR of 0.8Ω.

This is illustrated on the right. The vertical sensitivity of the oscilloscope was 10mV per division and the height of the pulse was about 30mV. This means that the capacitor's ESR was approximately 0.3Ω (the capacitor under test was a 330µF 50VW aluminium electrolytic).

Measuring Capacitor ESR

by Geoff

http://geoffg.net/Measuring_ESR.html

Recently, while selecting components for a power supply, I came across the following statement in the datasheet for the voltage regulator... "The output capacitor must have an ESR of less than 3 ohms."

When I looked up the retailers who supplied the capacitors in my parts bin I found that none of them listed the ESR for the capacitors that they sold. So, somehow, I needed to measure this value.

After some research I came up with the simple approach described below. It relies on some good test equipment and, while you may not want to repeat the test, the results should be informative.

ESR

Equivalent Series Resistance (ESR) is the internal resistance that appears in series with the device's capacitance. No capacitor is perfect and the ESR comes from the resistance of the leads, the aluminium foil and the electrolyte. It is often an important parameter in power supply design where the ESR of an output capacitor can affect the stability of the regulator (ie, causing it to oscillate or over react to transients in the load).

You can buy ESR meters but I just wanted to know if any of the capacitors in my parts bin had an ESR of less than 3 ohms. So, how to test them?

$$\mathrm{Cs} = \frac{-1}{\omega \mathrm{Xs}}$$

We now have an equivalent circuit that is correct only at the measurement frequency. The resistance of this equivalent circuit is the equivalent series resistance ESR = Rs = Real part of Z

Add the Dissipation Factor

If we define the dissipation factor D as

$$\mathrm{D} = \frac{\text{energy lost}}{\text{energy stored}} = \frac{\text{Real part of Z}}{(-\text{Imaginary part of Z})}$$

$$\text{Then}\ \ \mathrm{D} = \frac{\mathrm{Rs}}{(-)\mathrm{Xs}} = \mathrm{Rs}\omega\mathrm{C} = (\mathrm{ESR})\omega\mathrm{C}$$

If one took a pure resistance and a pure capacitance and connected them in series, then one could say that the ESR of the combination was indeed equal to the actual series resistance. However, if one put a pure resistance in parallel with a pure capacitance (Figure 2a), the ESR of the combination is

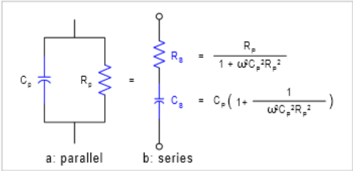
Real part of Z = Real part of

$$\frac{1}{\frac{1}{\mathrm{Rp}} + j\omega\mathrm{Cp}} = \frac{\mathrm{Rp}}{1 + \omega^2\mathrm{Cp}^2\mathrm{Rp}^2}$$

as illustrated in Figure 2b. From Figure 2a, however, it is obvious that there is no actual series resistance in series with the capacitor.

Ras = 0

But ESR > 0
Therefore ESR > Ras



C_p
R_p
=
$R_s = \frac{R_p}{1 + \omega^2 C_p^2 R_p^2}$
$C_s = C_p\left(1 + \frac{1}{\omega^2 C_p^2 R_p^2}\right)$
a: parallel
b: series

Figure 2: Series and Parallel Equivalent Circuits

QuadTech manufactures a wide variety of LCR meters designed for accurate measurements of C, Df and ESR. The design of the QuadTech 1930 LCR Meter, has been specifically optimized for high speed, low ESR measurements on tantalum and other types of capacitors. Fast settling time and quick open/short recovery significantly reduce test times especially on capacitors greater than 100µ F at 120Hz. The 1930 Low ESR Capacitance Meter performs most impedance measurements (C, Df, ESR, Z, R, X, L Q, Y, G, B, θ and DCR) over a frequency range of 100Hz – 100kHz. Actual voltage and current is measurable across the DUT.

The ESR of a Real Capacitor

Actual capacitors have three main sources of loss:
1. Actual series resistance: There is some resistance in the leads and plates or foils. This is the resistance of conductors

higher inductance in this test setup. I believe this was due to the fact that the smaller capacitor did not fill the package and internal lead inductance caused the effect. In this case, a 1 uF capacitor was a better choice than a 0.1 uF!

One of the advantages of this test is that the output waveform is the transient response of the capacitor. The voltages developed across the capacitor in this test are directly related to what will happen in a real circuit if the current risetime from the generator is similar to what the capacitor will see in its intended application.

was repetitive and the slight slope on the left half of the waveform was the end of the exponential fall from 5 volts. If a single pulse on a digital scope was used, the slope to the left of the Ldi/dt spike would be zero.

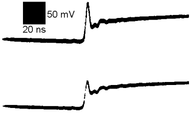


Figure 5. 1uF Capacitor

Figure 6 shows the result for a 1 uF radial ceramic capacitor (square case). Note the low inductance and undetectable ESR. Note also that the slope of the 1/C exponential rise is flatter indicating more capacitance than the 1 uF capacitor of Figure 5. This may be due to the fact that the electrolytic capacitor used for Figure 5 may have lower capacitance near zero voltage than at its operating voltage whereas the ceramic capacitor has a more constant capacitance with voltage. The inductance corresponding to the lower trace is estimated to be 4.4 nH.

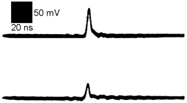

Figure 6. 1uF Ceramic Capacitor

It is interesting to note that a 0.1 uF ceramic capacitor in the same size package as the 1 uF of Figure 6 showed a slightly

and is always low. It causes a power loss I2Ras where I is the current flowing in the capacitor. This causes $D_1 = \omega \mathrm{RasC}$

2. Leakage resistance: There is some actual parallel resistance due to leakage current in the capacitor. We'll call this RL. It is the resistance of the capacitor at DC and it is a high resistance. For plastic capacitors it can be 10^12ohms (GΩ) or higher. It causes a loss of E^2/R_L where E is the applied (rms) voltage and $D_2 = \frac{1}{\omega R_L C}$. This loss is usually negligible except at very low frequencies.

3. Dielectric loss: This is due to two phenomena molecular polarization and interfacial polarization (dielectric absorption). It is not the purpose of this note to discuss its cause, but only its effect. It causes a D that can change with frequency in most any manner that is not abrupt. It acts neither as a series resistance, nor as a parallel resistance that would pass DC. One model is a parallel resistance, RD, which is variable with frequency, with DC blocked by a large series capacitance (CB) as illustrated in Figure 3.

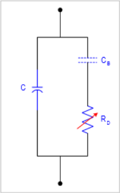

Figure 3: Parallel Resistance

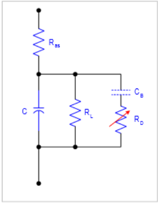

Figure 4: All 3 Capacitor Losses

If the series C were infinite, the D would be $D_3 = \frac{1}{\omega R_D C}$ but it must be remembered that it is not inversely proportional to ω because RD changes with frequency.

All three sources of loss are illustrated in Figure 4. This circuit would have a total dissipation factor equal to D1+ D2+ D3.

Plot of Total Dissipation

For the circuit in Figure 4, the total dissipation factor is

$$D = D_1 + D_2 + D_3 = \omega RasC + \frac{1}{\omega R_L C} + \frac{1}{\omega R_D C}$$

Figure 5 illustrates a general plot of this combination series and parallel resistance in a capacitance measurement.

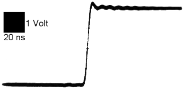

Figure 3. Input From Pulse Generator

Figure 4 shows data from a 4 uF electrolytic capacitor. The ESR offset is about 50 mV yielding an estimate of the ESR of just over one Ohm. Notice that there appears to be some oscillations on the 1/C part of the slope. This could be scope probe resonance or a resonance in the capacitor. The data was taken with a standard 10X Hi-Z probe, so the probe is suspect. I have seen capacitors with pronounced oscillation from internal resonance. If you are planning to put a large capacitor in parallel with a smaller one, especially if they are constructed from different technologies, it would a good idea to check out the impulse response of the combination using this method. It is possible for the smaller capacitor to resonate with the inductance of the larger one, causing an unexpected result.

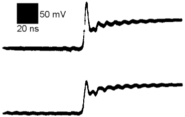

Figure 4. 4uF Capacitor

Figure 5 shows the result for a 1 uF capacitor of the same construction as the 4 uF capacitor tested in Figure 4. Note that the inductance is similar to the 4 uF capacitor, but the ESR is slightly lower. Since an analog scope was used, the waveform circuit to not significantly affect the initial current very much. For this frequency range a generator with a risetime of one to two nanoseconds will do.

If you need to check the capacitor using faster risetimes, it would be best to build the test setup on a small circuit board with a ground plane and controlled impedances. At this point, the parasitic capacitance of the 50 Ohm resistor would also be an issue to be taken into account. Fortunately, such accuracy is often not needed. Especially, if one is just comparing the relative performance of several capacitors.

Data

Figure 3 below shows the initial rise from the generator. The black square indicates the vertical voltage and horizontal time scales. The open circuit voltage was a little over 4 Volts with about a 5 nanosecond risetime. The data in Figures 3 through 6 were taken with an analog scope some years ago. Figures 4 through 6 show data obtained from several leaded capacitors (as opposed to surface mount). Two traces were taken for each capacitor. The lower trace was measured at the capacitor body where the leads entered and the upper trace included the minimum amount of lead to practically connect the capacitor to a printed wiring board. The upper trace would not be needed for modern surface mount capacitors unless one wanted to model the connection inductance from the capacitor to the point of interest on a printed wiring board.

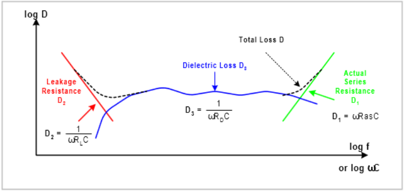

Figure 5: Total Dissipation Factor Plot

At any given frequency we could measure the real part of the impedance, Rs, or measure C and D and calculate it

$$Rs = ESR = \frac{D}{\omega C} = \frac{D_1 + D_2 + D_3}{\omega C}$$

Therefore ESR = $Ras + \frac{1}{\omega^2 C^2 R_L} + \frac{1}{\omega^2 C^2 R_D}$ and thus ESR > Ras, always.

Usually, ESR is very much larger than Ras. However, when ω C is large at high frequencies, high capacitances or some combination, the actual series resistance can cause the largest part of the total D. (See plot.) For very large capacitors (like 0.1F), ESR can be very nearly equal to the actual series resistance even at low frequencies (such as 120 Hz). For most capacitors at low frequencies, the actual series resistance is only a small part of ESR.

For complete product specifications on the 1900 Series Impedance Meters, or any of QuadTech's products, please visit us at http://www.quadtech.com/products. Call us at 1-800-253-1230 or email your questions to info@quadtech.com.

1) $dv/dt = i/C = 50$ mA/C
where C is the value of the capacitor at this low voltage and the risetime of the current << RC.

The offset between the baseline and the beginning of the exponential rise is just the voltage that the current, 50 mA for this case, develops across the ESR of the capacitor. The ESR can be easily estimated in this case by dividing the voltage offset (labeled ESR in Figure 2) by 50 mA.

Parasitic inductance in the capacitor will cause the spike in the waveform shown in Figure 2 exceeding the value of the dotted line along its length. If the current rise were in fact a ramp with constant slope and very sharp corners (high di2/dt) then the spike would be a square pulse of value:

2) $E = L*di/dt$
where L is the parasitic inductance of the capacitor.

The current rise from the generator used for the data in this article was not a ramp with very sharp corners and constant slope (the case for most generators I have used). That characteristic of the generator combined with probe effects led to a peaked shape to the Ldi/dt spike as shown in Figure 2. Using equation 2 the inductance of the capacitor can be calculated. Often, one does not need to calculate the inductance or ESR but just choose a capacitor from several available ones that has the lowest inductance and/or ESR.

Soldering the components onto a BNC connector as in Figure 1, works up to 300 MHz. I estimate the inductive reactance of the loop formed by the capacitor and resistor to be about 20 Ohms at 300 MHz (estimating the inductance at 10 nH). This is small enough relative to the 100 Ohms of resistance in the

For a pulse length that is long with respect to the RC time constant, one will see an exponential rise to the open circuit voltage of the pulse source. For the purposes of this discussion, we will be looking at the first couple of hundred millivolts of a 5 volt exponential rise. An example of this appears in Figure 2.

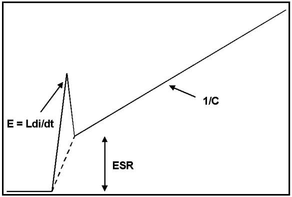

Figure 2. Initial Rise

Figure 2 shows the beginning of the exponential voltage rise across the capacitor when the generator pulse starts. The vertical scale is about 200 mV and the horizontal time is a small fraction of the RC time constant of 100 Ohms and the capacitor being measured. Since the capacitor voltage is still very small compared to the 5 Volt open circuit output of the generator, the current through the capacitor may be presumed to be constant and equal to the generator open circuit voltage divided by 100 Ohms, 50 mA in this case.

The risetime of the current will be the same as the generator voltage. If the rise is a ramp with a constant slope and the capacitor had no inductance, the initial rise shown in Figure 2 would follow the dotted line and then the slope would change to the initial slope of the exponential rise determined by:

Measuring Capacitor Self-inductance and ESR

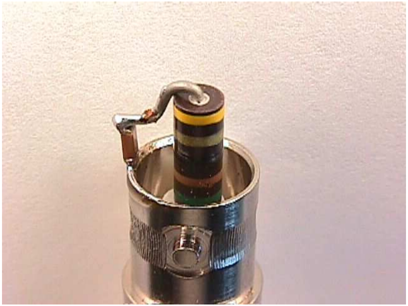

Figure 1. Test Circuit for Measurement of Capacitor Self-inductance and ESR

Technical Background

The parasitic parameters of a capacitor, that is its equivalent series resistance (ESR) and its inductance, affect the way the capacitor performs in circuits. Some applications are very sensitive to these parameters. For instance, a bypass capacitor used between power and ground in a digital circuit must be able to supply current quickly to nearby active devices. If it has too much inductance it will not be able to do this.

Similarly, the transient response of a capacitor used to divert a current pulse due to electrostatic discharge is very important to the ability of the capacitor to do its job.

So how can the parasitic parameters of a capacitor be measured? One could certainly connect the capacitor to a network analyzer and get a very good characterization. Such an instrument can be quite expensive though. Even the less expensive capacitance measuring instruments may not be available when needed. Both instruments may not provide the information in an easily usable form. If you have a pulse generator (preferably with a 50 Ohm output impedance) and an oscilloscope, you can easily measure the transient response of a capacitor. From this data the capacitor's ESR and inductance can be determined.

First, construct the simple network shown in Figure 1 at the end of a 50 Ohm coaxial cable fed from a 50 Ohm pulse generator. A 50 Ohm resistor is used in Figure 1 to terminate the coax during the rising edge and provide a total of 100 Ohms of source impedance. The resistor shown is a 51 Ohm 1/2 watt carbon composition resistor with one lead trimmed so that the resistor just seats with the trimmed lead fully inserted into the BNC connector. It may be necessary to put a little solder bump on the resistor lead so that it stays firmly in the BNC connector. The capacitor to be tested is connected between the end of the resistor and the shell of the BNC connector. An oscilloscope is connected directly across the capacitor using leads as short as possible to connect the probe. Probes with a resistive input impedance of 500 to 1000 Ohms are recommended. Standard 10X "Hi-Z" probes often have rising edge effects that will distort the part of the waveform used for the calculations.

NOTES:

NOTES:

INTRODUCTION

In March of 2009 while shopping for some sensors on ebay, quite on a lark I typed "Crystal Radio" as a search term not really knowing what to expect. My search was not totally random, I have always been interested in radio communications and in radio propagation as a geophysical probe of the ionosphere, (more about that here). Additionally as a child I had once a small "Spy Pen" crystal radio what always facinated me, and as an adult I had given a crystal radio toy kit to my second son who showed much interest in computers and electrical things. He has since gone on to his Master's degree in EE and now workd designing computer chips at Intel in Silicone Valley. So, maybe it was the radio?

Vaguely I thought to find a crystal radio or radio kit of some sort to play with, something more serious than a cheap plastic toy. What I found was suprising, so much there. I explored the listings, odds and ends mostly of course, its ebay after all, and a few completed radios new and vintage, and one in partictular which caught my eye. There were several kits by someone calling himself Xtalman including one he calls Dunwoody which seemed to exactly fit my idea, a kit, easy enough for a beginner but serious enough to satisfy a more educated mind. I decided to pull the trigger, the radio was offered "buy it now", so I did! So began my journey into a black hole of interest, somebody really ought to post warnings on all crystal radios.. "WARNING, may cause serious refocusing of lifestyle".

In the time since, I have plunged deeply into the web literature, joined the Xtal Set Society, and built homebrews of my own in addition to purchasing a few sets, (described separately). In the following pages I present each radio with the ideas and motavations that move me to own, admire, and use them. It has become a facinating journey for me which I wish to share so that others may understand and catch the bug for themselves, so that other radio builders may view and comment, with suggestions perhaps for improvement, and so us newbies may heed the WARNING, and STILL take the plunge!

The Xtal Set Society Dedicated to once again building and experimenting with radio electronics Great source for plans and books, kits and parts. I joined the society as soon as I finished my Mystery Set.

Dave Schmarder Dave's Homemade Radios, literally 10's of different sets all with interesting features and each a pleasure to look at. Much technical background and good design ideas can be found as well. I like this page.

Scott's Crystal Radios Mount Your Own Crystals Here I learned, and successfully applied, a good technique to mount my own crystals.

Part 2, Inspiration:, Sites with radio plans and projects, so many ideas.

Mike Peebles Crystal Radios - Peebles Originals!

Tom's Handmade Radios Nice selection of radios, superb craftmanship, for sale!.

Birmingham Alabama Crystal Radio Group Nice contest page, many lovely contest radios

Jim's Crystal Radio Page Crystal radios with ferrite cores, and a Mystery Set.

Larry J Solomon Solomon Radios, several variations on the Mystery Set and others..

Rainer Steinfuehr Gollum´s Crystal Receiver World.

So Many more, if I missed your site my sincere apologies.

The Stay Tuned Website is probably the site I visit most often of all. This excellent effort contains an enormous amount of information, vintage plans and projects, Contest Radios, Museums, and more. Download Professor Coyle's coil calculators, you will use them constantly. This is the only source for MB Sleeper's 101 radio receiving circuits I have found.

The Smith-Kettlewell Technical File ENERGY-FREE RADIO: THE CRYSTAL RADIO SET REVISITED This is also a great introductory page with a great deal of design tips and background. There is no author and its embedded in an eye research center website, oh well.. I highly recommend this page.

Owen Pool WB4LFH Crystal Radio Resources Owen Pool's great site with much fundamental background, projects, teaching, contest results and so much more.

Steve Mcdonald VE7SL Radio Notebook Crystal Radio DXing Great site for discussions of DXing with crystal radios and double-tuned design fundamentals.

Mike Tuggle DESIGNING A DX CRYSTAL SET Mike's discussion of his Lyonodyne-17 and the concepts behind its design.

Dick Kleijer crystal-radio.eu
Dick Kleijer's site contains great discussions of theory and the results of numerous experiments with his crystal radios.

Radio hobby in general and certainly crystal radio is a mentored hobby with most practitioners able and willing to help one get started and do well in this hobby. In my researches for information I have been greatly aided by the many helpful web resources built by this community. I wish to offer here my sincere thanks for your efforts. I certainly would not have come as far as I have without this help! The following list is only partial to the number of sites I visited and if your page is not listed I offer my apologies. This list represents those sites I found most significant and helpful in terms of 1) Crystal Radio Fundamentals and 2) Set Design Inspiration.

Part 1, Fundamentals:, Sites where I spend most of my time.

Lance Borden BORDEN RADIO COMPANY The start of my adventure, serious crystal radio kits, a seriously fine gentleman.

Kenneth A. Kuhn Crystal Radio Engineering Kenneth Kuhn's excellent pages on the fundamentals and design of crystal radios and all their associated parts, excellently written, accessable to the non-specialist yet precise and clear. I spent hours studying these documents.

Alan R. Klase CRYSTAL SET DESIGN 102 Alan Klase's site is chock-a-block full of great work and ideas for interesting sets. His Design 102 gave me good insights in the various incarnations a crystal radio may take.

More disturbingly, it takes the joy out of the hobby. Mercifully, my handy dandy wave trap goes a long way to solve much of the trouble, but not far enough. I need to direct my efforts in trapping this station now.

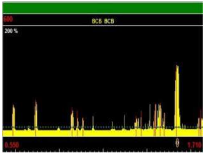
Question: Is this spectrum normal? Is it common for one station to so dominate the scene? I sometimes wonder if they arent cheating on their power output there. I know, probably not. My next project may be finding a way to use this energy to charge my batteries or light my house, or heck, to power my radios! The following plot shows that while by day I am merely in trouble, at night things are near hopeless. The band scan is a night spectrum. Sad thing is, I don't partictularily care to listen to sports on radio, (or television for that matter).

CHAPTER I

Resources for Theory and Design

Some thoughts on KGOW 1560 "The Game".
http://www.lessmiths.com/~kjsmith/crystal/kgow.shtml

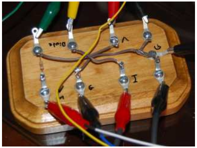


Over the months of playing with my hobby, my radios, learning, reading, i have come across a small fly in the ointment of an otherwise very enjoyable hobby. From time to time while listening to my radios I would find the airwaves filled with a single station, KGOW blasting across my entire tuning range. It was curious and interesting at first, radios would receive strong clear signals with or without a crystal or rectifier which seemed to me thoroughly at odds with what I supposed I was learning about how radios work. Discussions on Rap-n-Tap provided some, but not deep insights into my problem. Mostly I was advised to check twice and thrice all my connections. The most frustratingly bothersome aspect was that, it affected all my radios. Maybe my antenna and/or ground was responsible. Even when hooking up my "Sleeper #1" (shunting a diode across the phones) gave me the problem, in fact gave me the problem in spades. Turns out I am able to receive KGOW clearly merely by attaching the antenna and ground across the phones, no diode, no nada.

Looking somewhat deeper into the mystery, I chose to look closer, not at my antenna and ground, but at the BC band itself. Using my Icon R75 and RxPlus software, I made a band scan of the BC activity. What I found was most troubling for my location. The plot below shows a screen capture of the scan. Clearly KGOW stands out 2 to 3 times stronger than any other local station. It dominates the scene and saturates my post.

My radio "laboratory"

http://www.lessmiths.com/~kjsmith/crystal/lab.shtml



Having now acquired several crystal radios by purchase (two) or building my own (four), I begin to wonder how they stack up against each other and against other radios I read about and dream of on the net. It can be fairly common to hear radio performance described in qualitative terms, "high Q", "sharp tuning", "highly sensitive", etc. Without measured numbers to back them up, it is extremely difficult to judge the subjective notes of different radio users. It is inevitable I believe that in this hobby that one ends up getting together as much test equipment as possible, (read "affordable") in order to know more objectively about the radios one builds and/or uses. This page is the tale of my own effort to equip a small "laboratory" of sorts for just such purpose.

My first needs were related to my building projects and included meters for measuring capacitance and inductance. I have excellent-quality bench meters for other hobby projects including a Keithley 192 and 181 voltmeter with IEEE 488 computer interfaces. These are voltmeters only though, nothing else. My first purchase then was a capacitance/inductance meter. It worked great for capacitance, but the lowest range for inductance, 20mH unfortunately is useless. So, this meter was quickly followed by a stand-alone inductance meter ranging down to 200uH. I use these frequently when making or measuring coils, and measuring capacitors purchased on ebay, better to design a radio around a specific componant.

My next needs follow logically, what about the radios I build?, how do they do? For the non-electrical engineer, testing radios is a bit of a daunting task and this page is by no means intended to be a tutorial. I do give my experiences so that perhaps someone with the same idea may benefit and possibly avoid the mistakes I have certainly made. I describe my equipment and the protocols used in my testing, but I STRONGLY refer the reader to the following two pages for technical guidance and explanations, most of what I do came directly from here:
Dick Kleijer crystal-radio.eu http://www.crystal-radio.eu/enqmeting.htm
Gollum´s Crystal Receiver World
http://home.snafu.de/wumpus/gollum/testing.htm article by C.A. Lauter
I heartily express my appreciation to our European friends for making available on the web these excellent technical tutorials for crystal radio testing.

with a surface area of 1,600 square feet. The native lead occurred along a part of the margin of the ore body in a zone about 9 inches thick separated from the wall rock by clay gouge. The ore generally was argentiferous steel galena partly or completely altered to cerussite and anglesite with minor minerals including wulfenite, litharge (?), quartz and limonite. The native lead occurred as threads, sheets to one-half inch thick and pods up to 4xIX2.S inches.

sheared, massive, and 'steel' (a dense, extremely fine-grained, almost cryptocrystalline type). Sheared and steel galena textures were caused by post-ore shearing of coarse-grained galena and it was not uncommon to find the three varieties side-by-side. These textural variations had important implications for exploration because the more massive and free-grained types, which are less friable, were not affected as much by oxidation. As galena was released by erosion from the oxidized vein subcrops, it tended to develop a protective white rind of the Pb sulfate anglesite, and to collect downhill from the vein as a dispersion (float) train.

THE GEOLOGY AND MINERAL DEPOSITS OF THE TOBY-HORSETHIEF CREEK MAP AREA, NORTHERN PURCELL MOUNTAINS, SOUTHEAST BRITISH COLUMBIA., OPEN FILE 1990-26. By Alasdaire Pope
mine consist of massive panidiomorphic galena, sphalerite, pyrite, sucrosic cerussite and banded dolomite, galena, sphalerite and pyrite. In hand specimens bleischweif texture (steel galena), indicating deformation by simple shear (McClay, 1980) is frequently seen.

PROCEEDINGS OF THE THIRTY-THIRD ANNUAL MEETING OF THE N4INERALOGICAL SOCIETY OF AMERICA AT BOSTON, MASSACHUSETTS.
NATIVE LEAD, PRESIDIO COUNTY, TEXAS JORRN T. I_ONSDALAEN D KATHRYNO . DICKSON University of Texas, Austin, Texas
Approximately 3,000 pounds of ore containing native lead was recovered from three small tabular ore bodies in the western part of the shafter District, presidio county, Texas. Two of the ore bodies were vein-like in limestone with clay gouge walls. The metallic lead was localized at the centers of the veins. The third ore body was flat lying disk-shaped about 4 feet thick

DIODE TEST.. Describes protocols and results of testing many different diodes, diode classes, crystals, and even two different vacuum tube diodes.

DIODE PROTOCOL.. Describes a useful protocol for determination of Diode Is, n, and Ro.

DIODE CALIBRATION.. A simple set of modelled characteristics with variations in Is and n.

RADIO TEST.. Describes protocols and results of radio performance testing on my sets.

Conclusion

So, for an investment in a few key pieces of good equipment, yes at some non-trivial cost, you can appreciate the hobby so much more. I have an oscilloscope as well, but so far have not explored its value. I prefer the recording and spreadsheet methods as they give a better record of the results and allow graphing and easy comparison. Knowing how your sets perform, being able to test your diodes, knowing your coil inductance are all important aspects of knowing your radios. I certainly recommend this!
Ciao!

Steel galena owes its fine-grained texture either to mechanical deformation of larger crystals or to a beginning transformation to anglesite. It is supposed to be rich in silver but this is by no means always true. $PbS+4O=PbSO_4$ (Anglesite)

Geology of Colorado and Western are Deposits By Arthur Lakes, 1893.
A coarse galena is generally poor in silver, while fine grained "steel galena" is generally rich in silver, but the reverse may also be the case.

Waldschmidt, 1921. Hecla East Vein, Coeur d'Alene
The coarsest galena examined showed cleavage faces from 2 to 4 mm, square, but generally it is much finer grained than this. The fine-grained galena is commonly known as steel galena because freshly fractured surfaces have a steel-like luster. In all the specimens examed, this steel galena appeared to be in an intimate mixture of galena, tetrahedrite, sphalerite, pyrite, gnague, and other minerals present in the ore.
It appears that the original ore body consisted chiefly of galena, sphalerite, pyrite, pyrrhotite, tetrahedrite, freibergite, quartz and siderite. When movement took place along the O'Neil Fault and possibly along with minor slips, the ore body was grreatly crushed, during which time the galena acted as a putty-like mass for the suspension of broken fragments of the harder minerals. This breaking resulted in the formation of the typical steel galena.

Great mining camps of Canada 1. The history and geology of the Keno Hill Silver Camp, Yukon Territory.
Keno Hill mineralization "silver-lead-zinc veins in lastic metasedimentary terranes". Galena is present mainly as the common coarse-grained, well-crystallized and friable type, but also displays several other textures, such as fine-grained,

ANTENNA TUNING

Notes on simulations for a Tuggle Front End

http://www.lessmiths.com/~kjsmith/crystal/atu.shtml

By Kevin Smith

Introduction:

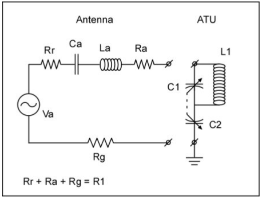
When designing my radios I always make extensive use of Mike Peebles and Dan Petersen's "Professor Coil" spreadsheet. This tool along with the many tutorials and explanations online have vastly eased the design work around homebrew coil winding. We can now model a coil with good accuracy prior to the actual job and thus better match the coil to the other components we plan to include. One quickly becomes aware that most coils for the broadcast band vary around a nominal 220 or so uH. More than this and most variable capacitors will have too much bottom-end capacitance to tune the top of the band. Less than this and you need caps with fairly high values when fully meshed, 500+pF or more.

All the above is pretty straight forward. On the other hand, when I have been reviewing double-tuned set designs, I often note that the coil used for the ATU (antenna tuning unit) will have an inductance quite a bit lower than the main tank coil. Professor Coil doesn’t address this aspect of coil design and I have found little discussion online concerning ATU design. Mostly this seems to be dealt with in passing or as a digression when dealing with other subjects. The most useful web sites for addressing this aspect of crystal set design include Dick Kleijer's excellent work and Ramon Vargas's detailed analysis of the "Tuggle Front End", that’s about it. Neither site discusses the ramifications of varying different parameters such as the Earth Resistance, Coil Inductance, etc although Kleijier's site includes a great calculator page to allow one to ask these questions. In my explorations of ATU design (primarily Tuggle) I have made extensive use of Kleijier'e page and for this I am deeply in his debt. My hat's off to Dick, thanks so much.

The following discussion presents the results of many models cranked through the design calculator. I wished to understand what factors play main roles and which have minor parts.

For a conventional detector-circuit coil one can pretty much control all the main factors, really only the inductance and capacitance of the circuit. The main and only surprise comes in the form of "stray capacitance" resulting from the spacing of the coil wires. This can readily be 1) guessed at and 2) minimized by good coil winding technique. For the antenna circuit by contrast many of the needed parameters, earth resistance, antenna capacitance and inductance, and antenna resistance in the forms of actual wire resistance and radiation resistance are, for most of us, unknown and only guessed at. The following figure illustrates the antenna and ATU with a list of the main "components" that need to be understood and/or modeled.

The Antenna Equivalent Circuit consists of an AC voltage source Va (the signal of interest), in series with some radiation resistance Rr, antenna capacitance Ca, antenna inductance La, antenna resistance Rr, and finally a ground

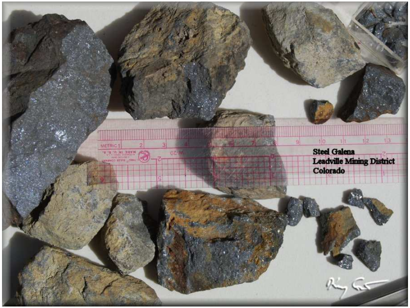


Steel Galena
Leadville Mining District
Colorado

From Leadville Colorado, the specimens below are the best examples of "steel galena" I have yet come across. The samples have a dull weathered surface skin deep hiding a massive, fine-grained lead-silver mining ore of a classic Rocky Mountain type. On a fresh surface the sample has a fine texture and flat grey color. This is not museum material, and its difficult (to impossible) to locate on ebay, but its the real mccoy when it comes to crystal radio. Don't even bother with the pretty pretty Missoury galena, it rightly belongs behind a glass display, not in a radio. Chips from this sample, potted in woods metal, rectifies strongly almost regardless of where the cat's whisker touches, instant sound.

Steel galena is difficult to find for sale due primarily to its lack of excellent crystal cleavage. Galena, as is well known, has beautiful LARGE crystal structure. Who would buy that ugly-looking grey junk?

Kevin



resistance Rg for the return path to complete the circuit. In addition the ATU consists of a coupling capacitance C2, and a tank with inductance L1 and capacitance C1. The capacitance and inductance of the ATU is needed to tune out the reactance of the various components of the antenna for which we do not have data. What to do?

Without an antenna analyzer (expensive) one can only estimate the many component values based on published antenna models. Ken Khun's engineering page has a number of nice models and a good discussion of the antenna parameters we will be trying to understand and use. For my personal setup my antenna consists of about 75' of 14awg wire averaging about 10-12' high and with another 25' of lead-in. For such an antenna Khun models a 30m antenna 3m high which approximates my situation closely enough. Wire resistance is negligible as is the radiation resistance which he shows to vary between some 0.1 to 1.5 ohms. Such an antenna is capacitive by nature and will have about 220 - 375pF along with some small 20uH inductance, not too far off a standard "dummy" antenna. This pretty much leaves earth resistance Rg as the main unknown parameter.

For Rg one has the option of punting and taking the "Standard" value of 25 ohms. In my modeling I have found this parameter to be critical and highly sensitive. I do not recommend guessing here, it is recommended one go to the internet page of their state, county, or local government and search for reports on ground or soil resistivity (or conductivity). As this is an important agricultural and engineering parameter, it has been surveyed for most places and should be available with some effort. Effort well rewarded. Earth resistivity for the Texas Gulf Coast is a mercifully low 10 - 15 ohm meters, but for many regions this will not be the case.

Earth resistivity depends on a number of variables including the material, moisture, mineral salt, and temperature. A table of typical ranges in ohm meters for some different soils follows:

Loam	5	-	50	ohm meter
Clay	4	-	100	
Sand/Gravel	50	-	1,000	
Limestone	5	-	10,000	
Sandstone	20	-	2,000	
Granite	1,000	-	2,000	
Slates	600	-	5,000	

Moisture up to about 17% dramatically lowers resistivity, mineral salts are needed and pure water is an insulator, and as the temperature approaches freezing the resistivity also rises dramatically. All this factors into your estimation of Rg. The actual resistivity seen by the circuit depends on the earth resistivity and the type of grounding system you have installed. The more metal in the ground, and deeper, the lower the resistance. Know thy earth! A map of USA soil resistivity follows:

"Substitution of other atoms for lead in galena is not very extensive. Among the elements which do accur in small amounts are: Sb, As, Bi, Ag, Ti, Zn, Cd, Fe, Mn and Cu. In many cases these may be present in impurity minerals (acanthite Ag2S, sphalerite, chalcopyrite, etc.) rather than in the galena structure."

Why is this interesting for the radio engineer? The following is my own theory, (speculation mostly). Most of you who have worked with galena detectors have noted that hot spots generally occur on or adjacent to fractures, lines or discontinuities on the crystal face, seldomly on the smooth lustrous face itself. Rectification occurs at the junction of two minerals, or of a mineral with a cat's whisker metal. Many explanations have been offered, most having to do with the position and nature of the crystal lattice at the point of contact, and the perceived presence of "impurities" (atoms other than lead) in the galena crystal matrix. As noted above, "Steel Galena" is a often an ore of silver containing not only galena, but abundant admixtures of associated minerals generally too small to see and thus seldomly described except in detailed mining reports as above. In addition, the very small grain size of common steel galena allows numerous physical and mineral discontinuities on the small detector surface area, and thus numerous hot spots. I speculate that many/most of these hot spots may in fact be at the junctions of galena and other minerals along with the light contact of the ever-so-sharp cat's whisker itself. Other galena (lead) deposits such as the Missouri / Tri-State region are not associated with silver mineralization (Tri-State ores typically have only about 30ppm Ag). These show large museum quality crystal faces but have poor detector properties.

"The coarsest galena examined showed cleavage faces from 2 to 4 mm, square, but generally it is much finer grained than this. The fine-grained galena is commonly known as steel galena because freshly fractured surfaces have a steel-like luster. In all the specimens examed, this steel galena appeared to be in an intimate mixture of galena, tetrahedrite, sphalerite, pyrite, gnague, and other minerals present in the ore."....
"It appears that the original ore body consisted chiefly of galena, sphalerite, pyrite, pyrrhotite, tetrahedrite, freibergite, quartz and siderite. When movement took place along the O'Neil Fault and possibly along with minor slips, the ore body was greatly crushed, during which time the galena acted as a putty-like mass for the suspension of broken fragments of the harder minerals. This breaking resulted in the formation of the typical steel galena."....

In this ore, galena is NOT the silver-bearing mineral. Rather, the silver is in the freibergite and to a lesser extent in the tetrahedrite. Very interesting. Quoting from classic mineralogy texts on galena I find the following:

Dana's Manual of Minerology: (Hurlbut)
"Pb 86.6, S 13.4 per cent. Silver is usually present, probably as admixtures of silver minerals such as argentite or tetrahedrite."

Elements of Mineralogy: (Mason and Berry)
"Commonly, galena is very nearly pure PbS. The silver, arsenic, and antimony reported in chemical analyses are largely due to the inclusions of argentite of tetrahedrite, small amounts of which are difficult to detect in a black opaque mineral."

An Introduction to the Rock Forming Minerals: (Deer, Howie and Zussman)

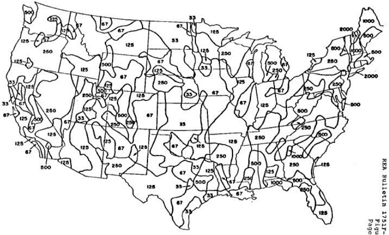


FIGURE 2

Estimated Average Earth Resistivity in U.S. (ohm·meters)

Modeling:

All the above discussion is great but... What is important really? The following section presents the results of applying different parameters to get a feel for the sensitivity of it all. To begin with I need explain my base assumptions. All the models are based on Kleijer's calculation spreadsheet which requires inputs for the following parameters:

Frequency
Coil inductance
LC circuit Q unloaded
* Complex impedance of antenna or
Series Resistance (Rg+Ra+Rr)
Series Capacitance Ca
Series Inductance La

* If the series values are given, the complex impedance is calculated.

1) Frequency is chosen per your interest, I have taken models at F = 550-1100-1700 kHz.

2) Coil inductance one has control over when winding. I have chosen base values that resonate with about 400pF tank capacitance, with some sensitivities.

3) Unloaded Q I do not have. For modeling I have taken Vargas's measures for a 4.5" coil wound with 660/46 Litz wire. I assume this will be about as good a coil as one can wind. I also made a sensitivity for lower Q. Q is a function of frequency and I have used the appropriate value of Q to match the modeled frequency.

4) Series Resistance is basically what the earth and ground system will deliver plus a small 1-2 ohm contribution from Ra and Rr. I have modeled four cases 10, 15, 25 and 50 ohms. The first two cases reflect my needs on the Gulf Coast with low resistivity soil. The 25 ohm case is a "typical" or "standard" grround. Finally, many will have much higher resistivity soils and you need to know just how difficult things can get!

5) Series capacitance I based for my specific antenna on the model of Ken Kuhn (Mathematical Model of Wire Antenna). The capacitance of a 30m antenna 3m high he calculated to range from 220pF and low frequencies to 375pF and high frequencies. I input the correct capacitance to match the frequency modeled.

6) Series inductance I just input 20 uH every time.

Some thoughts on "Steel Galena" and its use as a crystal detector/rectifier for radio waves.

http://www.lessmiths.com/~kjsmith/crystal/sgalena.shtml

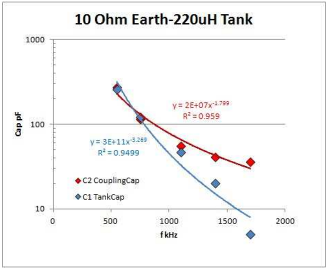
I have recently become interested in crystal radios and am especially interested in the "cystal" in the radio. This is due to my background as a geologist / mineralogist / petrologist / oil exploration geologist. I have read in several radio websites concerning steel galena describing it as argentiferous as well as fine grained and useful as an excellent detector with numerous hot spots. While commonly associated with silver ores, I have never read of galena itself as being much silver bearing as a mineral. This puzzle sent me to the web to see what I could find on this "steel" variety.

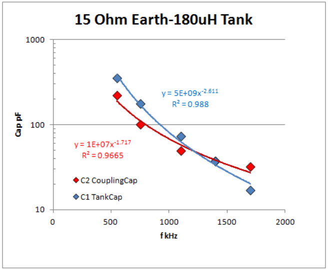
Steel Galena does indeed associate most closely with silver ore deposits, especially in the classic Rocky Mountain silver districts like Leadville in Colorado, Coeur d'Alene in Idaho, and Tintic / Park City of Utah. In all cases the ore bodies themselves are in sheared and altered sedimentary rocks. Mineralization is due to hydrothermal movements of water with movement aided by the sheared, and crushed zones having fine to extremely fine grain size, hence its name "steel".

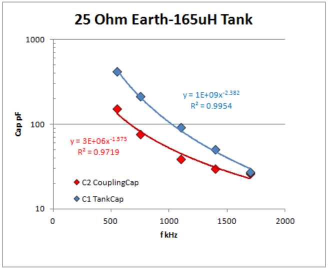
To give a sense of the deposits themselves I wish to quote a couple accurate petrological descriptions:

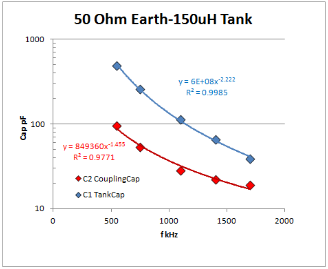
Waldschmidt, 1921: Hecla East Vein, Coeur d'Alene

The data and plots for four different scenarios follow:









The above plots show the calculated capacitance versus frequency for four different models of Earth Resistivity / Tank Inductance. In each case I maintain the same log capacitance

vs frequency scale for easy comparison. The cases modeled represent increasing earth resistance presented to the ATU from a very low 10 ohms to a fairly high 50 ohms. Actual earths can go up to two orders of magnitude higher. I chose L1 inductances such that the maximum needed capacitance would approach 500pFs, easily found on many variable caps. With respect to the coupling cap (C2, red curve), as the earth resistivity increases the needed capacitance declines. The tank cap value needs to resonate with the inductor and increases with smaller-value inductance. In searching for a 500pF max cap value, the choice of inductance needs to decrease with increasing earth resistance. Parameters other than Rg, L1 and C1-C2 have minor impact on the models.

Conclusions:

From the plots one can readily see that above 10 ohm earth the two variable capacitors on the ATU do not track well. As the earth resistivity increases, the worse the tracking. Most locations are not blessed with a low resistivity earth and this needs to be factored into the ATU design. There is little to be done, changing the design coil inductance will change the needed capacitance on BOTH C1 and C2, (larger L1 leads to smaller C1 and C2 for resonance and vice versa). A possible solution well worth trying is to use a dual-gang capacitor where one section has a different value than the other, the above plots give an easy way to decide the max values needed. Use the smaller gang on the coupling circuit and the larget on the tank. Experience tells us that ganging the capacitors on a "Tuggle" front end works well, but from the models I have to imagine one might squeeze a bit more performance by giving up the convenience of one-dial tuning on the ATU, especially where your earth has a fairly high resistance.

The best design concept will be to know first and critically your earth resistance. If this is just a guessed-at parameter then I strongly urge you to put down the Litz, set aside the silver-plated caps, store the holy-grail diodes and go do some research on your local ground. All the time, expense, and effort on the greatest "state-of-the-art" crystal receiver will be wasted if the ground is not attended to. If the resistivity of your earth is high in ohm-meters, get more metal in the ground or consider a counter-poise. The following table from LEM Instruments shows the relation between earth resistivity in ohm meters and actual earth resistance in ohms as a function of the earthing method used.

Models and Data:

10 ohm / 220 uH Lowest resistivity Earth Case sensitivities

Professeur Jacquemard Poste a Galene
http://www.lessmiths.com/~kjsmith/crystal/jmrd.shtml

A bit of a mystery this one, I am hankering to build a breadboard repro of the set if only to play with this bizarre (to me) circuit.

data and information on the set is not small, but not enough:

from the schematic:
L1: form 25mm dia, 68mm long selenoid, 170 turns 4/10 wire
calculation- 0.4mm-26awg wire, 220uH coil
L2: ID 25mm, W 8mm. OD, #turns, guage not given
L3: ID 20mm, OD 34mm. W, #turns, guage not given

estimation from photo:
L2: OD about 32-35mm, wire guage is small in the 32+ range
L3: W maybe 6-8mm, wire guage is small in the 32+ range

from book:
MW = 545 - 1500 Kc
LW = 157 - 272 Kc

from calculations:
MW tuning with 220uH typically 365 - 450 pF

from clues in the two publications
1. most Vcaps are 450pF
2. most GO coils 120turns x two coils

CHAPTER V

Other Thoughts and Speculations

Coil Q:

http://www.lessmiths.com/~kjsmith/crystal/coilq.shtml

Kevin Smith

Introduction:

I have been building and studying crystal radios for some time now and slowly begin to learn a few things about these marvelous sets. In this section I begin my exploration of coil, coil quality and that mysterious dimensionless factor, Q... This page thus is a bit preliminary as I have not yet begun any measurements to determine the Q of my coils. Please bear with me.

My purpose here is to present some facts and data that has resulted from my explorations of the web. I have often wondered at what the quality factor of my coils should be and as often realized that I really do not have any expectations as to what is possible. Now, having dome some research, I can with some confidance say that this is solved. Coils as used in crystal radio broadcast band reception typically employ coils with Q factors ranging from 100+ (pretty lousy) through the several 100's (decent) and on up to 1000 or more for those remarkable Big-Litz wonders ($$$). Knowing the expected (or actual) Q of your coil is important in so far as it impacts the choice of diode to be used in the set. On my page of Diode Calibration I present a summary graphic which indicates how the diode Rd value relates to the tank parallel resistance Rp. This Rp in turn is a function of the coil Q. Schezzam! So here we are.

In your set construction, with a good effort and good engineering practice one can easily expect to wind a solenoid coil in the Q = 200 range without much trouble, even with a cardboard form, sealed, of course. With various "open" coils, spiderweb, basket weave, diamond weave, etc. you may expect to double that.. possibly. The advantage in open coils derives from first the separation between adjacent wire turns which reduces self-capacitance in the coil, and secondly from the obvious lack of a form. All materials used in the coil will have some amount of dielectric losses associated with them and the less material used the better. Air core coils are best in this respect. I am not here to speak about ferrite coils as I have no experience with them. Frankly, they seem (to me) a bit like cheating.

The following graph presents data that I have scoured off the web. My primary sources include Hund and Groot, 1925*, Wes Hayward, Dave Schmarder, Ken Khun, Mike Tuggle, Steve Ratzlaff, and Dick Kleijer. 10,000 thanks for those who post their data on the web! The following plot gives the Q value as a function of coil Rs (series resistance. In striving for a high Q coil, in effect one is eliminating losses and lowering the series resistance as much as possible. There is more to it of course. The Q formula Qu = 2pifL / Rs tells us that Q is also a function of the coil inductance L and the frequency f of the measurement. All measurements chosen for plotting are made around 1 Mhz and most of the coils are in the L = 200 - 350 uH range. So, despite the formula, in this plot the coil Rp is the main driver. From the plot it should be apparent that winding a coil with Q = 200 or better should be a no-brainer. If your coil Q is less, you just aren't trying. At the high end, Q's > 1000 seem to be pretty extreme and these coils are expensive. You better be using big Litz 660/46 and use a basket design (although the two best coils on the plot were solenoids).

ANTIQUE RADIO

By Marc Ellis

Mailbag Time Again!

It's time once again to give our readers the floor. Receiving mail from you is certainly one of the most enjoyable parts of this job! It's instructive, it's fun, and it keeps me in touch with your interests—which is a great help in planning the column.

My way of responding to your letters is to acknowledge them on these pages. If I tried to respond personally, particularly to the many requests for schematics, technical advice, and other information, I wouldn't have time to write *Antique Radio*.

So instead I share the letters, referring the questions and requests to the readership at large and passing along the many interesting tips and other pieces of information. For maximum impact, and in order not to interrupt the flow of ongoing projects or stories, your letters are saved up and put together, in a special column or two, three or four times a year.

Since it does take another couple of months after I write a column for the magazine to hit the streets, it can be six months or more before you see your request or comment in print! So please be patient.

Here's a pictorial of the reproduction 1922 British crystal set built by reader D.B. Millar from plans in Practical Wireless *magazine. The set was tuned by swinging the front pancake coil over the back one.*

CRYSTAL SET COMMENTS

The series of articles on the NBS crystal set drew a lot of attention, and I'm still receiving comments from readers on that subject. Let's start with one from *Rudolf Mangold* (Penn Valley, CA), who remembers building crystal sets with his dad in the early 1920's. Even though the NBS set was designed to be scratch-built, Rudy doesn't understand why a capacitor wasn't used across the phones. The phones act as an RF choke, attenuating the flow of current through the crystal unless bypassed. "If we would show a crystal set without a capacitor at our radio club, we would be laughed at." Rudy and his dad made their own phone capacitors by sandwiching alternate layers of metal foil and tissue paper.

D.B. Millar (Annapolis, MD) built a kind of British equivalent of the NBS set from vintage plans published in the UK magazine *Practical Wireless* (September, 1972). It was offered as a means for listening to the BBC 50th anniversary program (November, 1972) commemorating the first broadcast in 1922. That set didn't have a phone capacitor either, but (using a formula from Ghirardi's *Radio Physics Course*) Millar built one from aluminum foil and masking tape—rolling up the "sandwich" into a neat cylinder.

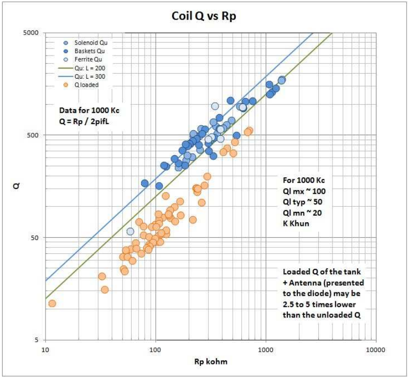
Many folks who don't have the patience to fool with a cat's whisker (myself included) like to substitute a modern semiconductor diode for the galena while experimenting with crystal-set circuits. *George H. Haby* (Altadena, CA), who is 88 years old, goes us one better by using *four* diodes hooked up as a standard full-wave rectifier. The input terminals are connected where the crystal normally goes; the output terminals to the headphones.

Vincent Bashore (San Ysidro, CA) received his first crystal set as a birthday present in 1928, then got into building them. He once gave up school lunches for a week to accumulate parts money for a set using a coil wound on a maple rolling pin and tuned by a brass slider.

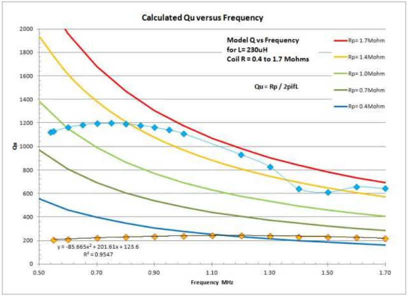
A photo received from *Robert S. Davey* (Frankfort, IN) shows a set he built from plans in *Popular Mechanics* (January, 1977). The published set used a 3½-inch-diameter, cylindrical salt container as a form, but Bob seems to have used some other kind of tube. For flexibility in experimentation, he substituted clip-lead coil connections for the permanent ones suggested in the article.

A. Ross (1926 Hafor Circle, Iowa City, IA 52246) is looking for two of the references I mentioned during the NBS set series: *How to Build Your Radio Receiver,*

Popular Electronics, March 1995



On the plot I also post in orange circles my estimate of what the loaded Q presented to the diode (Antenna + Tank) might look like. Loaded Q will always be lower than the unloaded Q by several times. I have estimated that high-end sets (big litz, silver-plated ceramic insulated caps, best wiring practices) may lower the Q by about 2 1/2 times (B Tongue's performance set has Q = 700). At the low end (vintage components, small solid wire coils, taps) the load may lower Q by up to 5 times. Ken Khun in his excellent web book states that typical sets at 1Mhz have a loaded Q between 20 and 100, 50 typical and this is where most of the data falls. I scaled the divisor by Qu to produce the above plot but note that this is merely an estimate. Somewhere some bloke has no doubt tuned a big litz coil with cheapo capacitors. Having an idea of your set's Ql will allow a better selection of the proper diode for matching.



The above plot is from a series of measurements on two of my coils kindly made for me by Steve Ratzlaff, AA7U. The blue diamonds are the measurements on a 660/46 Litz basket beast and the yellow diamonds are measurements on a modest 18awg tapped solenoid wound of a cardboard form. The data from the low Q coil form a lovely continuum across the BCB band while the litz coil data above 1MHz or so seem to be declining and erratic. Steve measured the coil a great many times and found good consistant results. The measurements are excellent but I must say, I am a bit suspicious that the high-Q coil may be at the limit of the HP Q-meter calibration, or perhaps 660/46 litz Q tops out at 0.7-0.8 MHz and crashes above that. (I have not yet found time to persue this). The plot

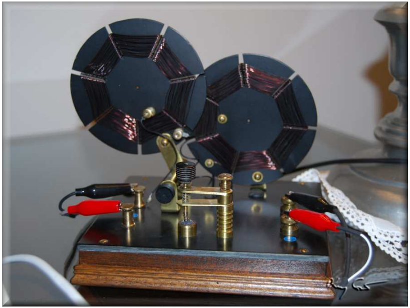
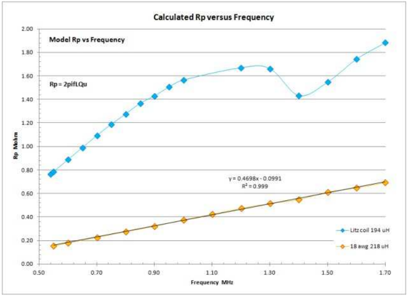
plans? Or, was this a kit? As I cannot locate an actual copy of the Sept 72 journal, I still can only speculate. I do hope it is a true homebuilt.

The following photos show the set and the references mentionned above.



Portrait of the beauty..

also includes Q vs f curves at constant Rp values. It is clear that, while tuning across the BCB spectrum, the Rp of the coil changes continuously.



Calculating the coil Rp from the data (Q:C:f), I have reproduced the above graph of the coil Rp vs frequency. It is evident that the trend follows a perfectly straight line for the low-Q coil. I would expect a similar straight-line relation for the litz coil but again things look strange. My impression here is that of a much steeper Rp vs f relation where the calibration on the Q-meter breaks down near 1MHz (Rp ~1.5 MOhm) and the data wanders until a second linear trend (with about the same slope) is re-established between 1.4 to 1.7MHz.

Now time for a few calculations, just how good can a coil Q get?

The following calculation is made to determine the AC resistance of the Litz wire used in a coil:
From different Litz wire manufacturing sites one can find tables and data allowing the calculation of the resistance of your favorite litz wire.

The formula for the D.C. resistance of any Litz construction is:

Rdc = Rs (1.0515)^Nb * (1.025)^Nc / Ns

Where:
Rdc = Resistance in Ohms/1000 ft.
Rs = Maximum D.C. resistance of the individual strands (4544 for 46awg wire)
Nb = Number of Bunching operations (assume = 2)
Nc = Number of Cabling operations (assume = 1)
Ns = Number of individual strands (assume = 660)

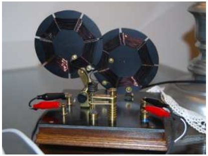
Rdc = 4544 (1.015)^2 (1.025)^1 / 660 = 7.27 ohms / 1000 ft.

The ratio of AC resistance to DC resistance of any Litz construction is:

Rac/Rdc = S + K (N Di / Do)^2 * G

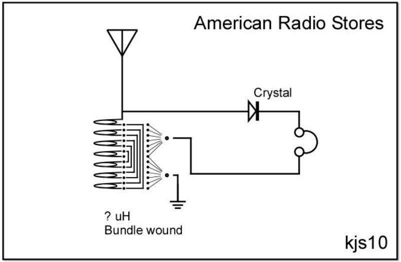
Where:
S = Resistance ratio of individual strands when isolated (1.0003 for 46awg wire)
G = Eddy Current basis factor = (Di * sqrt(f) / 10.44)^4
F = Operating Frequency in HZ (assume 1MHz)
N = Number of strands in the cable = 660
Di = Diameter of the individual strands over the copper in inches = 0.0016

BBC 1922 - 1972 Commerative
http://www.lessmiths.com/~kjsmith/crystal/bbc.shtml



A bit of a mystery this one, I found this radio on ebay and it was just SO pretty that I had to have it. The circuit is a simple variometer of pancake-coil design. Being a variometer has its drawbacks such as limited sensitivity and gawd-awful selectivity. If this piece wasn't so darned cute I would let it adorn the shelf indefinately. The set does have one mysterious element for me. Who made it? When? Some research on the web resulted in two interesting discoveries and an added mystery. On Darryl boyd's excellent web site I found in the plans section a mention of this very set, or one very near to it taken from the March 1995 issue fo Popular Electronics. The reference was to the September 1972 British journal Popular Wireless, the text I have shamelessly copied and placed below, the critical text highlighted in red. I subsequently found an image of the cover of the Prac Wireless issue with the set nicely featured. So, I have to assume this set is homemade at or soon after the publication of the plans in that issue. I assume the set was made in USA, but cannot be sure at all.

The new mystery? well, if you look closely at the radio I have, the drawing in the Pop Electronics article and the photo of the radio on the Prac Wireless cover, you will see virtually the EXACT SAME set right down to the hardware and placement. Only a few minor differences. My mystery then is this, was this an extremely faithful homebuilt version from detailed



Circuit schematic for the set.

AMERICAN RADIO STORES, INC.

Portrait, set and box.

Do = Diameter of the finished cable over the strands in inches = 0.056
K = Constant depending on the number of strands = 2

Rac/Rdc = 1.0003 +2(660*0.0016 / 0.056)^2 * (0.0016*1000 / 10.44)^4 = 1.393

Therefore the AC Resistance of 660/46 litz wire is approximately:

The A.C. resistance is: 1.39 * 7.27 = 10.13 ohms/1000ft.

A 5inch diameter basket weave coil made from 660/46 Litz wire having an inductance of 230 uH will typically require some 40 turns or about 53ft of wire. At 10.13 Ohm/kft, that comes to an AC wire resistance of 0.53 ohms for the coil alone. Were all the losses represented by series resistance of the wire, the coil would have, at 1 MHz an unloaded Q = 2700! Naturally, wire resistance is not the only source of loss in the tank. There is a capacitor, metallic objects intruding into the magnetic field of the coil, diaelectric losses, eddy current and other losses. Its no wonder that the best coils just top out above Q = 1000 or so.

This is where I leave things. Time to get measuring. Below I provide my input data, have at it!

Kevin Smith

*Note that in 1925 the importance of coil Rs was understood, but the factor Q was apparently not used. I have taken (quite painfully) the L and Rs data from their plots and calculated the resulting Q. I recommend to those interested to download the pdf of their paper.

Inside I expected to find a typical tapped selenoid, the box is certainly large enough for one. What I found suprised and rather shocked me. It still does! The coil is bundle-wound, a mass of 26-30 dcc wire about 2.25 inches diameter. I was unaware that such a design would work. It is impossible to check how the tap wires are attached, they seem to just get wound into the coil with no apparent connection. It appears to be continuous wires from one switch set wound around and around and then exiting to the second switch set. That sounds like eight independent coils wound together. Another odd circuit characteristic is the fact that the tap points between the two tap switches are wired to each other (see photo and schematic). Perhaps connecting in such a manner combines them into a single longer coil, hard to speculate. How this coil works is different from anything I have experienced in crystal radio. Completing the schematic, rectification takes place via an ordinary cat's whisker and small potted galena crystal, whew! This is certainly an interesting design if not otherwise efficient or selective. It is a welcome addition to my small menagerie of vintage sets.

American Radio Stores, Inc.

http://www.lessmiths.com/~kjsmith/crystal/ars.shtml

An interesting vintage crystal set recently came up for bidding on Ebay, an American Radio Stores, Inc radio in good working condition. This set interested me because, from the photos provided, it looked to have a fairly classic 1920's circuit with tuning accomplished via two switches to taps on the coil. I presumed that they are units and 10's taps as outlined on the classic Bureau of standards Circuar #121 set. A modest bid brought the radio to my doorstep a couple weeks later.

Looking at the radio when it arrived showed me that this was, even for the time, a fairly inexpensive set lightly built with cheap but workable parts. As expected, the radio has fair sensitivity and abysmal selectivity. (Recall, I bought it for the classic design not its DX potential). Somewhat to my consternation, the front panel was attached to the box by four small brads that could not be removed. No chance to view the inductor in the interior without compromising the vintage nature of the radio. I agonized over the question of whether to tear into the box or preserve the radio. After deliberating some 30 - 40 nanoseconds I was scheming for the most efficient and least destructive procedure to access the interior. My handy Dremmel neatly sliced the small brads one by one leaving no marks on the box or panel.

An Analytical Approach to the measurement of coil Q

http://www.lessmiths.com/~kjsmith/crystal/coilqm.shtml

Kevin Smith

Background:

Measuring the values of your radio components is an interesting and fun part of the Crystal Radio Hobby. Not only does it help you design better radios, but helps to understand the physics behind the wires and plates. The radio coil, one of the principal components is generally that part wound by hand. All other components, diode, variable capacitor are usually bought ready-made. The coil sits at the heart of the set and yet it remains devilishly difficult to measure and characterize. Even cheapo inductance meters, (I mean, my cheapo meter) do not properly measure the coil inductance at radio frequency. Coil quality, well that is a whole other matter. Quality, or the Q-factor as it is often called is a bench-intensive and measurement-intensive proposition that even the most dedicated radio fan may shy away from.

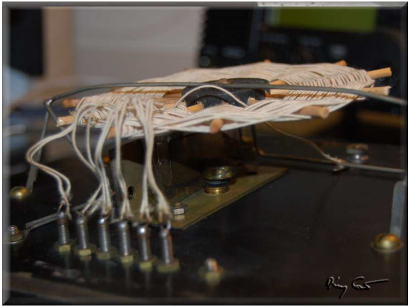
If you wish to know your coil Q-factor you have the choice of tracking down and paying a lot of money for an old HP or Boonton Q-Meter, or setting up a test bench and making the required measurements yourself. A number of techniques for measuring the Q of a coil have been published and excellent summaries can be found in "Q Factor Measurements on L-C Circuits" by Jacques Audet, and "Experiments with Coils and Q-Measurement" a web page by Wes Hayward.

All the techniques discussed involve variously setting up a parallel or series tank containing the coil to be tested and an accompanying capacitor to tune it to the needed measurement frequency. The tank is generally energized with a signal generator and measured with an oscilloscope or sensitive digital voltmeter. Other components often may include attenuators, SWR analyzers, Spectrum analyzers etc. Sources of error enter with coupling, loading, uncertainty as to the actual internal resistance of the source generator, and the need for several independent measurements which are then multiplied or divided together, adding additional error. All this works very well for the engineer with good bench practice, good equipment ($$), and the patience to perform the measurements several times to check repeatability. All these things plus the required anality coefficient the current author lacks.

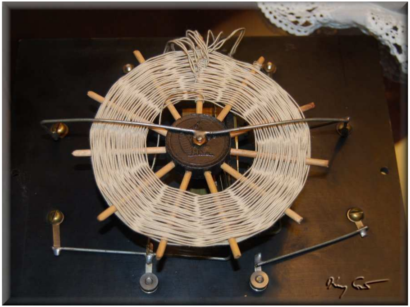
In this paper I propose an alternative approach that takes an analytical look at the oscillating tank waveform and determines the coil Q from that. This technique dispenses with a majority of the equipment involved with traditional methods but does require a digital oscilloscope. In recent years the affordability of these scopes has greatly increased. If you have a digital scope, or access to one, or were looking for an excuse to purchase one, then read on, this technique may be for you.

Some Theory:

The inspiration for this technique is certainly not new. I first found the following simple circuit, (Figure 1) on page 22 of Bucher’s 1919 "Wireless Experimenter’s Manual". Having a good deal of experience capturing and evaluating damped radio oscillations for a Spark Gap transmitter, I immediately saw the utility of the circuit for a simple Q determination based on the damping decrement of the tank.



A peek, such as it is, at the set condensers and cam tuning assembly.



The spiderweb coil with vintage cloth-covered wires, taps and wireing.

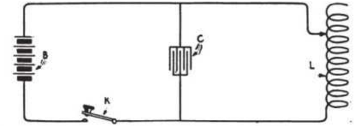


FIG. 8. Simple oscillation circuit illustrating the production of radio frequency currents.

Figure 1. Simple oscillation circuit, Bucher 1919.

As a professional Geologist, I must admit that most math involving more than ten fingers and ten toes (for advanced computations) is not my specialty. As such I will keep this aspect to an absolute minimum. Still, a bit of algebra may be useful to explain damping and logarithmic decrement. RF oscillations in a tank circuit are damped due to losses (primarily resistive) associated with that circuit. The amount of damping thus is related to the quality, or Q of the tank. In old texts the damping is generally determined by measuring the "Logarithmic Decrement" or the amplitude of successive oscillation peaks and taking the log of the ratio.

$$d = \ln(A1/A2) \qquad (1)$$

A more generalized version of this formula taking into account measurements over many periods can be expressed as:

$$d = 1/n \ln(Ao/An) \qquad (2)$$

Where n is the number of periods analyzed, Ao is the amplitude of the first peak and An is the amplitude of the peak n periods away. This equation allows a very simple determination of the log decrement with high accuracy. Because damping is due to resistive losses in the circuit, it can be related to the circuit components as follows, (Bucher, 1919):

d = pi (R / 2pifL) (3)

The angular frequency is often expressed as w= 2pif so this can be substituted into equation (3) above to simplify as

d = pi R / w L (4)

We turn now to looking at Q and its relation to the circuit components. The general expression for Q is:

Q = 2pifL / R (5)

Simplifying to

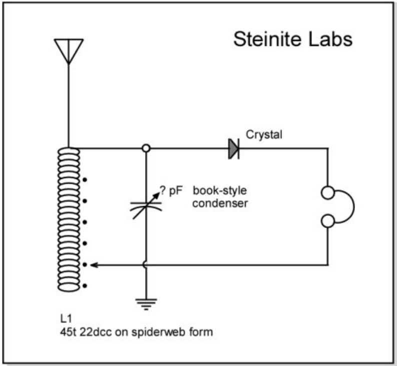
Q = w L / R (6)

With the term w L in both expressions, we can solve for w L in each and set them equal to each other:

QR = piR / d so:

Q = pi / d (7)

Dreadful, wasn't it? The inspiration here is that with a simple determination of the logarithmic decrement, deriving the circuit Q is a trivial exercise even a geologist can manage. No signal generators, no attenuators, no multiple measurements. All this should serve to reduce sources of error and give a faster and easier way to determine the quality of that most central component of your crystal radio, the coil.



Circuit as best I can make out

Portrait of the Steinite set

Setup:

The following schematic shows the setup, (Figure 2). In this configuration, I have used a simple 9V battery to stimulate the coil and have the scope connected to the tank via a coupling coil. An earlier configuration with a power supply resulted in too much noise and ripple to obtain a good reading. The tank is coupled lightly to the scope with a coupling coil. This coupling coil is simply two turns of hookup wire about 4 inches in diameter placed an inch or two from the coil to be tested and I have found no reason to space it further. Between the coupling coil and oscilloscope I utilize the 1:100 probe although testing with my 1:10 probe showed little impact. In this way, the coil under test is clean and well isolated from the measurement circuit.

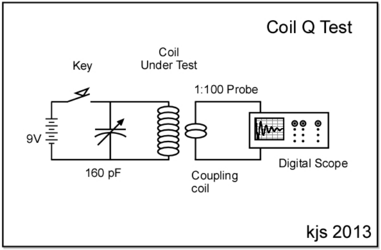


Figure 2. Schematic of test circuit.

For the tank I have used a small CT1C150 military spec cap ("APC"-type) with a capacitance range from about 20 to 160 pF. These are silver or nickel plated (depending on the source of information) and ceramic (steatite) insulated and should have a high Q with little impact on the test. At least this is the general assumption used in most Q-measurement articles I have run across. In actual fact the capacitor Q is not infinite and not even that high so resistive losses associated with the capacitor can be expected to lower the measured Q. One needs to keep this in mind and know that this measurement is on the resonator, not on the coil itself. More on this topic in a later section. The APC capacitance range is limited but sufficient for my intended test frequencies of 1.0 to 1.1 MHz, this is a test, not a radio.

Keying, or pulsing the circuit is somewhat tricky. In order to obtain a clean wave trace the pulse contact needs to be fast and sharp. Contact "bounce" and arcing, especially at radio frequency are difficult to avoid and pulsing the circuit several times may be needed prior to finding a clean trace. I initially used a transmitter key but found the contactor at RF to be messy with visible arcing. The best method I have found for pulsing the circuit is to connect a pointed probe to one side of the circuit and tap it sharply but lightly against the hot side of the battery. After a few tries one gets a "feel" for the contact. Pulse the circuit and get a wave, things are this simple.

Procedure:

Hang the coil under test on a stand where it is clear of other components or metal objects. Connect the coil as per the schematic. Connect the probe and scope to the coupling coil leads and set the scope for a good scale, (Figure 3). I generally use 5uS / division horizontal scale which gives me 40 to 50 oscillations at about 1 MHz. For higher Q coils I may go to

---

A Vintage Steinite

http://www.lessmiths.com/~kjsmith/crystal/steinite.shtml

Steinite standard from the mid-1920's. This set has lost its decal but not its classic look. It has a good condition enclosed crystal detector which works very well, binding and phone posts and labels in the typical Steinite lettering. Six taps on the interior spider-web coil and a mica and brass plate "book-style" condenser complete the tuning of this unit. Inside all the components are original with original soldering. It is unfortunate that the condenser is not working as expected. Peering in between the coil tap wires I can see what appears to be 3 or 5 brass plates separated by mica dielectrics. The tuning dial on top turns a shaft with a small cam that alternately compresses the plates together and lets them spring apart. I can see only the outside plate returning to its open position when the cam is open, the others remain compressed so the variation in capacitance is minimal. Well, I can enjoy one station. In fact the tuning is very broad so when "running" the radio has two or more stations competing for my attention. Well, its lovely just the same.

The following photos show the set and its interior.

10uS / division for a longer recording. Set the scope trigger appropriately to capture the data.

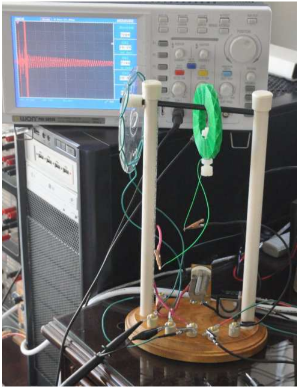

Figure 3. Photo of the test setup.

Tap, or "key" the battery to pulse the tank and review the waveform on the screen. Setting the scope on its measurement mode allows reading the wave frequency with each pulse. Adjust the capacitance after each pulse to bring the tank to the desired frequency, near 1 MHz in my case. Once at the desired frequency you are collecting data. When you get a good clean oscillation free of contact hash and noise, send the data to the computer for analysis. For my scope set at 5uS/div it returns

5000 data points to the computer. At 1 MHz that is about 100 data points per cycle, more than enough sampling to avoid any question of aliasing.

The decrement measurement is based on measuring two peaks. The data is in digital format so one should eliminate "estimation error" by actually reading the value off the spreadsheet, noting both time (in uS) and amplitude. Before taking readings, care must be taken to center the oscillations around zero. Amplitude measurements assume that the waveform is symmetrical around zero yet the scope may or, more likely, may not be set perfectly for this. In the spreadsheet the solution is simply to take the average of all the readings and subtract that from each.

Type the values for “to” (initial peak time), “tn” (final peak time), Ao (initial peak amplitude) and An (final peak amplifude), and the number of periods analyzed “n”.

T = tn - to in uS (8)
f = 1/T in MHz (9)

d = 1/n ln(Ao/An) (10)
Q = pi / d (7)

Next, disconnect the battery and coil and measure carefully the capacitance, C, that was used in the test. With this you can calculate the actual coil inductance from the frequency and capacitance. Why buy an expensive L meter?

L (uH) = 1E6 * ((1/ 2pif)^2) / C (pF) (12)

Example One:

CHAPTER IV

Radios I have acquired (read: paid waay too much for, with no regrets)

An example to show off a bit. This test was made with a close-wound tapped solenoid on a 3" cardboard form. The graphic in Figure 4 shows some initial contact hash followed by a lovely damped oscillation. Measurements on this coil showed a test frequency of 1.055 MHz, L of 215 uH and C = 106 pF. Q was calculated at 167. A decent coil but not great.

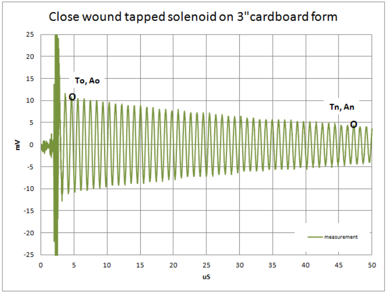

Figure 4. Oscillogram of a coil under test.

n = 45
T = (tn - to) / n = (47.24 - 4.59)/45 = 0.948 uS
f = 1/T = 1/0.948 = 1.055 MHz

Ao = = 11.2 mV
An = = 4.80

d = 1/n ln(Ao/An) = 1/45exp(11.2/4.80) = 0.01883
Q = pi / d = 3.142 / 0.01883 = 167

To test the validity of this technique we need a bit more theory, just to be certain this is working. With the data in spreadsheet form, it becomes possible to model the coil from a theoretical standpoint. The model can then be plotted with and compared to the acquired data to test for correlation. Various web pages, especially university-sponsored lab exercises provide a good source for practical techniques and their theoretical underpinnings. Some good sources I utilized include:
"Damped oscillations in RLC circuits" by Barbara Dziurdzia at AGH University of Science and Technology in Cracow, "RLC Circuits" a lab note from Rice University, and "Oscillations and Resonances in LRC Circuits" from Durham University in the UK. And very many others.

From the above we find the general equation for damped electrical oscillations as:

qc = qo * e^(-a*t) * cos(2pif * t + phi) (13)

Where
qc is the charge in volts
qo is the initial charge
a is the damping factor (=Rs/2L (series) and = 1/2RpC (parallel)
R is the coil resistance in ohms
L is the coil inductance in uH
t is the time in uS
f is the frequency in MHz
and phi is the phase angle

The phase angle and qo charge are initial conditions and adjustments should be minor to fit the calculated oscillation to actual. L, the inductance comes from the calculation we made with equation (12), and frequency comes from equation (9).

Schematic of the kit, (AnyKits.com) A005. The kit is configured with a maximum gain between 45 and 50, too high for headphones but too low really for listening with the speaker easily. You will note the location of R1 (in series with a 10uF capacitor) between pins 1 and 8 on the LM386. If you short the resistor leaving only the capacitor, then the gain will increase to the maximum of 200. If you do such a project, I recommend you download the LM386 datasheet from National Instruments.

This leaves the resistance of the coil (R) as the primary variable. Model the above equation in the spreadsheet by adjusting R until the model results match the measured oscillation from the coil. From the above example we see Figure 5 with the modeled damped wave overlaid on the test oscillation.

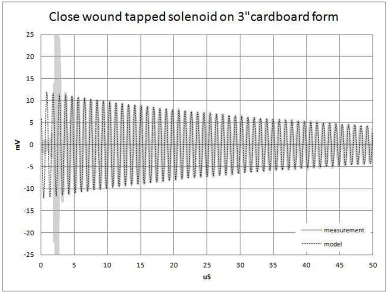

Figure 5. Oscillogram with modeled damped wave response.

Here the background data from the test is in grey and overlaying it is the dashed model in black. The fit is nearly perfect using a resistance of 0.22 Mohms. Relating resistivity to Q we have the following equation (5):

Q = Rp / 2pifL

Substituting f = 1.055 MHz, C = 106 pF, and R = 0.237 Mohms the result is Q = 167, exactly the same as with the decrement method. An exact match will not always be the case, but they ought to be fairly close. The match between theory and the decrement method gives confidence that this analytical technique is as robust as it is simple.

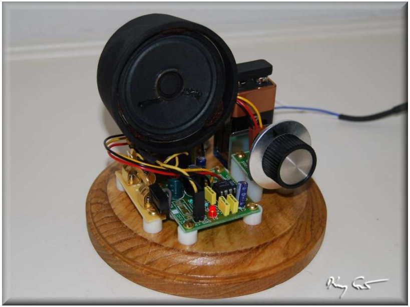
qc = qo * e^(-t/2RpC) * cos(2pif * t + phi)
qc = 12.2 exp(-t/2*Rp*106)*cos(6.283*1.055*t + 1)

Where t = 0 to 50 uS
R = 0.237 Mohm in this case for best match.

Q = Rp / 2pifL = 237000 / 6.283 * 1.055 * 215 = 167

Example Two:

To be sure the technique works I have also assessed the quality of a 5inch diameter basket weave coil wound from 660/46 litz wire. Such coils are rightly considered "performance coils" for their low skin-effect and low resistivity.



I was initially worried that the audio input impedance may cause me trouble. I read so much about this, impedance matching, transformers, etc etc, almost a fetish really. I have subsequently learned that the LM386 input impedance is about 800 Megohms, the 10k pot being the limiting factor. So, with considerable relief, I concluded this ought not present any problems with the crystal radio circuits. I find the amplifier works very nicely with my radios. The sound is as good as the Radio Shack unit.

The amplifier certainly adds to the vintage "look" of my setup. Well, you be the judge, I hope I come close, please check out the photos...

From the front, wooden base, full display of components, big adequate volume control..

crystal radios one builds with passion, creating something more than a mere radio, but a work of art, a piece of furniture. Still, the technology itself is primitive dating back to the dawn of radio. When I look at the mini amplifier, it looks like a toy yet inside there is the most wonderful technology, solid state integrated circuitry. We take this advanced technology and slap it inside a cheap plastic box, an appliance. Naturally, I don't complain about the price, but for my project I wish for something above.

The solution struck me as obvious, give the same care and respect for the amplifier as I do the radio. I also sought to maintain a "vintage" visual aspect for the unit, breadboard layout, antique binding posts and a large adequate volume control knob, (the pitiful volume control wheel on my RS mini has already come apart once and threatens to break at any time). I wanted a nice lacquered base and sturdy speaker enclosure. The enclosure was the main challenge. I finally ended up with a heavy plactic goblet from a local thrift shop cut down to a tapered cylinder into which the speaker can be placed tightly. The rest of the set is modular with plug-in connections for the audio in, power, speaker, and volume control potentiometer. A question, do I add a brass knife switch for the on-off? I worry I am out of room on the base. Still pondering this.

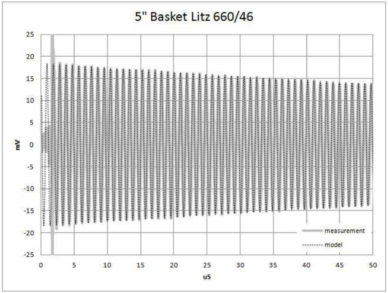


Figure 6. Second oscillogram with modeled damped wave response.

The coil tested values as follows:

n = 45
T = (tn - to) / n = (47.82 - 4.70)/45 = 0.958 uS
f = 1/T = 1/0.958 = 1.044 MHz

Ao = = 18.05 mV
An = = 13.65

d = 1/n ln(Ao/An) = 1/45exp(18.05/13.65) = 0.00621
Q = pi / d = 3.142 / 0.00621 = 506

And:

qc = qo * e^(-t/2RpC) * cos(2pif * t + phi)
C = 123 pF

qc = 18.55 exp(-t / 2*Rp*123)*cos(6.283*1.044*t + 1)

Where t = 0 to 50 uS
R = 0.627 Mohm in this case for best match.

Q = Rp / 2pifL = 627000 / 6.283 * 1.044 * 189 = 506

The results above for a big litz coil clearly demonstrate its superiority to a more common tapped solenoid. Published data though has let me to expect a big litz coil Q to be in the 1000+ range. I have run this test backwards and forwards, checking all possible causes for this unexpected low Q with no difference in the final value. In fact I am quite impressed with the repeatability of the technique and the correspondence between the results from the decrement and those from modeling the wave form.

To be certain I even tested the coil using the old -3dB method. As stated previously, I am uncomfortable using a signal generator in addition to the scope, and I have already found trouble connecting the 1:100 scope probe directly to the tank, as is necessary in this method. With that said, the results yield a bandwidth of 2.3kHz about a nominal frequency of 1018.8kHz for a tank Q = 450. I suspect the method (with the problems noted) lowballs somewhat the final result. In any case, this confirms the test to have a moderate Q and nothing like the expected values one reads online.

Notes on Capacitor Q and its impact on the measurement value.

This is where we begin to think more seriously about the capacitor used to resonate the tank. The assumption of very high Q needs to be questioned. I stated in the setup discussion

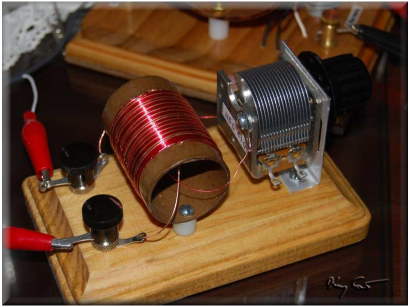
A breadboard Audio Amplifier

http://www.lessmiths.com/~kjsmith/crystal/amp.shtml

A little project stemming from my persistant difficulty in hearing. (Losing one's hearing is never fun to admit, but combined with crystal radio, well, its trouble!) I hope I do not offend any "purists" with this project. Still, I understand that many crystal radio owners keep a small amplifier too, for "those times" when, well, you know.. So, this amplifier project, its for, well, those times.. (I suspect Radio Shack would have discontinued their nifty Mini Amplifier years ago had it not been for the crystal radio community.)

My idea was to build my own unit rather than use a store-bought amplifier. Additionally, I wished to put my own stamp on it, make it unique. I started with a kit for the basic layout and electronics. I wanted to base things on the NI LM386 chip which is a good part and hard to break. I found several distributers of what appears to me as the exact same kit and so chose the cheapest $6 dollar kit. NI sells the LM386 for 34 cents a pop and would even provide a few "samples" but then I would be stuck laying things out and wireing.. Been there, done that. A printed circuit board is just SO much easier to use.

One of my inspirations for this project also stems from the nature of modern electronics in general, and the Radio Shack mini amplifier in partictular. Using my RS mini, I am always struck by the contrast between electronics new and old. With



Wave Trap

my opinion that the capacitor Q ought to be high enough as to not influence the coil Q measurement in any significant manner. I said that for three reasons: 1) Just about every published article starts with such an assumption and 2) I had not done much research on the subject of capacitor Q and so had no particular expectations other than assumption 1 and finally 3) I had no measurements or specific knowledge of the Q for the capacitor used in my setup.

Reason 1 is a punt and should be rejected, reason 2 has been remedied and I give some analysis on the interesting subject of capacitor ESR (Equivelant Series Resistance) on a separate page so that readers may set their own expectations. For the third reason I have received the kind assistance of Steve Ratzlaff, AA7U who offered to make actual Q measurements on the coils and APC capacitors with his HP4342A Q-meter, results follow:

Litz basket coil,
550kc 1127Q;
1000kc 1140Q,
1700kc 674Q (194.2 uH on aade.com LC meter)

Solenoid coil,
550kc 205Q,
1000kc 240Q,
1700kc 222Q (218.2 uH on aade.com LC meter)

Using Steve's Litz wound ferrite rod coil (1000kc 1047Q) as the reference for external caps:

100 pF silver mica (99.2 pF meter):859Q at 1068kc (Q meter alone and coil 1025Q)

APC cap with red/black leads (149 pF meter): 937Q at 904kc (Q meter alone and coil 1060Q)
APC cap with my Litz leads (149 pF meter): 995Q at 904kc (Q meter alone and coil 1060Q)

Steve's measurements above provide important datapoints with which to calibrate my technique. Note first of all that the Litz coil is not a modest 506Q but a robust 1140Q at 1MHz. The reason for my low measurement was my assumption of a high-Q capacitor. Steve's measurements of two of my APC's are 995 and 937, hardly very high. There is an obvious need for a correction. Wes Hayward in his excellent notes on Q measurements provides the key in the form of the following formula:

Ql = (Qc * Qres) / (Qc - Qres) (14)

where Ql is the desired coil Q, Qres is the measured Q of the tank/resonator, and Qc is the tank capacitor Q.

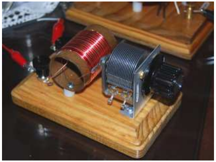
Substituting the values Qres = 532 and Qc = 995 the equation simplifies thus:
Ql = (937 * 506) / (937 - 506)
Ql = 1100.

The result is distressingly close to Steve's measured value of 1140Q. This shows the possible level of accuracy in the analytical technique used, both reassuringly high and very "Litz-like".

Taking the first solenoid and substituting the values Qres = 167 and Qc = 937 the equation simplifies thus:
Ql = (937 * 167) / (937 - 167)
Ql = 203.

Wavetrap, a useful gadget

http://www.lessmiths.com/~kjsmith/crystal/wt.shtml



This little gadget is most handy for crunching those local behemoths that always seem to be directing their strongest signals right in your direction. My wave trap is a bit of a combination of 1) Osterhoudt's QRM coil, 2) a design I found online on Owen Pool's excellent web site, and 3) a bit of my own seeing as how I had some, but not all of the ingredients needed from both traps. That is, I used what I found in the junk box.

The trap is formed on a stiff cardboard paper core with 1 1/4 inch outside diameter. On this I drilled holes for winding the tank coil, 110 turns of #30 awg enameled wire. Both Poole and Osterhoudt recommend #32, but 30 is what I had. Over this I would a coupling coil, 15 turns space wound of #22 awg enameled wire. Tuning of the tank is completed with a 410 pF var cap.

Tuning is sharp and deep, it takes a bit of getting used to, but then, schezzam!!!.. problem station gone! I luv it.

This is slightly low to Steve's measured 240Q. I am of the opinion that the original tank measurement may have been a bit on the low side. Still, again the results are within the ballpark and the technique works if you have a good measure on the Q of the capacitor used in your tank. Alternatively, starting with a known coil Q, the technique will work equally well to determine the Q of an unknown capacitor.

Conclusion:

If you have access to, or own a digital oscilloscope, or have been hankering to purchase one, then the time may be now. The analytical method presented above is simple in practice and robust in theory. I would also say that, by working with your wave forms, you learn to recognize your data and soon get a good "feel" for what is good and what is not. The technique also produces, should you wish, an auditable report of the wave and analysis. It is hard to argue against the results with the waveform sitting there staring right at you!

Measuring your coil Q should not be difficult.

A copy of the evaluation spreadsheet in xls format can be found here CoilQbyDecrement_kjs.xls

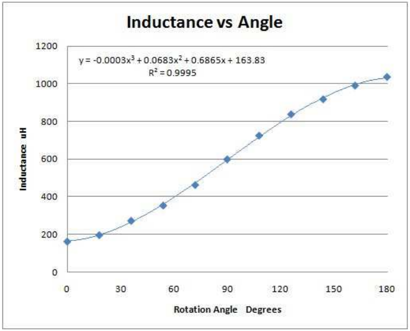
of the inductance versus rotation angle and a photo of the Variometer mounted in its stand, ready for use.



Perhaps the less-than-optimal condition was a factor, but I was in luck to win the coil with an only bid. I had no illusions that this was a long-shot deal, the chances of the variometer being functional were poor. My expectations were not deceived when it arrived sometime later. Nope, it didnt work. The question was, could it be restored, and just how did the thing work, how were the connections made anyway? Inspection quickly led to three obvious broken connections and an understanding as to how the connections were intended. A few dabs of solder later and under the meter I had a fully-functionning variometer! All that was left was to give the vintage coil a lovely stand to show it off.

Measurements of the Inductance show a large variation, from 163 uH to 1036 uH. This should give good duty to electrically "lengthen" my woefully short antenna. Shown below is a plot

---

Crystal Radio Capacitors and ESR

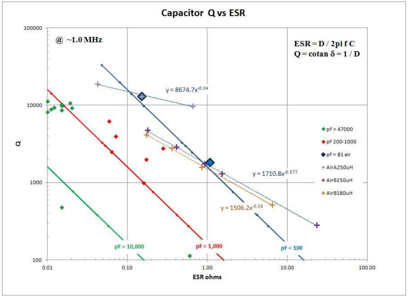
Kevin Smith

In my ongoing effort to understand crystal radios and the theory that makes them work I have recently turned to setting my expectations concerning capacitance. The tuning capacitor is, next the coil itself, the principal component of the set. Few builders fabricate their own tuning caps so I suppose it is possible to take them a bit for granted. I have been reading on the radio forums some threads concerning radio Q and the subject of the variable cap Q seems to be getting more attention. So, what is the deal?

I set about my study by gathering what I could find on the web and at the close of this note I include a short reference list of useful pages from which I extracted data the ideas. I wish to extend special thanks to Ben Tongue who, as usual, has provided the essential measurements and background. The plot below of capacitor Q versus Equivalent Series Resistance (ESR) summarizes my findings. It is a bit busy as there are a number of interesting and important ideas represented in the relationships presented.

Any discussion of component quality needs first to acknowledge that the fight to increase the component Q is in reality a fight to eliminate (not possible) or reduce as much as feasible the resistive losses associated with that component. It helps then to look not just at Q, but at how Q relates to the component ESR. There are two fundamental equations that describe this relation: 1) Q = cotan theta = 1/D. D is the dissipation factor and is an attribute of the dielectric material used in the construction of the capacitor. Equation 2) ESR = D / 2pi f C. This equation tells us that capacitor losses expected due to resistance are both angular frequency and capacitance dependant. It is important to remember that not all Q's are created equal. What we want is to keep the ESR to a minimum.

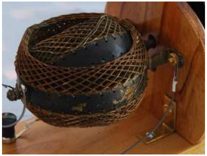
On the plot there are a number of data trends presented. Note first that both plot axes are logarithmic, it makes a difference on how one thinks of the data. Additionally, note that the plot is specific (mostly) for data at 1.0 MHz. I make the assumption that a cap that is superior at that frequency is likely to be superior across the BCB.



The first things to discuss are the three slanting lines. These are computed from a table of Dissipation Factors at 1.0MHz by Dr. Johnson. I have supplied the capacitances and calculated the resulting Q and ESR values. When one goes looking at capacitor data sheets or summary tables one is likely to find data computed at 100 KHz and 1.0 MHz (mercifully) but that

Vintage Variometer / Loading Coil

http://www.lessmiths.com/~kjsmith/crystal/lcoil.shtml



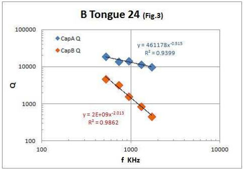
My receiving station is pretty typical I expect, decent ground, so so antenna and I have been hankering for some time to add a loading coil to my station to better match that antenna with my radios. Lack of urgency or just plain laziness perhaps have kept me from working on this project. Part of my hesitancy has been the idea of utilizing a variometer as a loading coil, and these are not easy to find.

Variometers are variable induction coils that function by being connected in series and changing the mutual inductance between them. Most variometers though have a relatively small range of inductances making them of limited suitability for, well, just about anything in crystal radio. They find a home mostly these days as a control for regeneration in such circuits. Alternatively they make a nice variable inductance load on your antenna, the purpose I was seeking. Only, I really wished to find/make something with quite a lot of wire to get a good range of inductances going. It was by some degree of luck I believe that I noticed some time back on ebay a rather beat-up looking variometer on offer. The variometer, shown below, was a basketball weave design and importantly, was wound in at least three layers suggesting a lot of inductance.

the likely capacitor data will be specific to caps in the uF range, or 10^6 higher that what we need in a crystal radio tank. Be careful not to get enamored with the high Q values occasionally quoted, check the capacitance. From the plot it should be apparent that not all Q's are created equal. Larger-value caps have lower ESR and so the Q's are often agreeably high. I have plotted a few specific cap measurements from various sources.

Two measurements should stand out; these are indicated by the larger blue diamonds. These are measurements by Bill Hebbert and presented by Ben Tongue in section B of his Article 24. I reproduce his Figure three below, with grateful apologies for the liberties I have taken,

By replotting Ben's figure I can calculate the relation between Q and frequency (table below) and so compute the estimated Q at any frequency. On my main plot I give Ben's Capacitor A and B for 1.0 MHz given the 250 uH inductor. Ben states that the plot assumes 20pF stray added. Since the capacitance needed to resonate at 1 MHz and 250 uH is 101 pF, I make the assumption his caps were set to 81 pF. This accounts for why the diamonds are set slightly off the 100 pF line of the plot. Given his Q measurements it is easy to compute the ESR for each cap. This is the world of the crystal radio builder. I include the ESR at the BCB endpoints for each cap as well to give the full picture.



pF		f	Q	
tank	cap	MHz	Cap A	Cap B
375	355	520	19000	4750
190	170	730	14000	3230
114	94	943	14400	1610
101	81	1000	*13148*	*1828*
60	40	1300	11600	870
35	15	1710	9800	460

for I = 250 uH and 20pF stray in tank
(Q data in italics is computed)

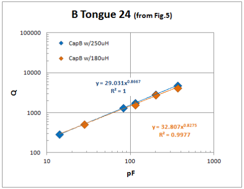
The quest for high Q is indeed a quest for low ESR as long as you work in the capacitance range needed. One interesting piece of advice I have occasionally seen is that, to increase your tank Q, it is better to use lower-value coils and higher-value tuning caps. As much of the losses in the tank derive from losses in the coil this makes excellent sense. I wish to ask the question what about those higher-value caps? The plot immediately suggests that moving to higher capacitance drives down the ESR, this is a good thing. It may or may not improve the cap Q but I am not sure it matters as long as resistive losses are minimized. To better set my expectations I have again turned to Ben's Cap B data.

The small plot below takes data presented in his Figure 5. Data presented include Q at various capacitances and frequencies. I cross-plotted his data for pF and Q for the appropriate frequencies using both 250 uH and 180 uH inductances. Reading the actual Q off the tiny plot was an estimate at best, but it is interesting. This allows one to estimate his cap Q at any capacitance setting. The table below

---

CHAPTER III

Accessories on Breadboards



provides the estimated Q, and calculated D, and ESR for the capacitances from Fig 5 (with 20pF stray added). The values of Q do not improve by moving to higher capacitances but the ESR of the cap is slightly (at low tuning freq) and well improved (at the high tuning freq). This is the goal. It is worthy to note that the tuning frequencies do not line up with the original data from Ben's Fig 3 as seen on my main plot. While Ben specifically noted that his figure 3 included 20pF strays, in his figure 5 he speaks in absolute capacitances. I did my best to correct for this but there remains some ambiguity in the presentation. The point remains though; moving to higher capacitances in the tank will lower the tank losses due to ESR.

250 inductor (w/20pF stray)

tank pF	KHz	D	Q	ESR ohm
385	513	0.0002083	4800	0.177
220	679	0.0003448	2900	0.404
134	870	0.0005714	1750	0.917
101	1000	0.0007638	1309	1.502
34	1726	0.0034973	286	23.046

180 inductor (w/20pF stray)

tank pF	KHz	D	Q	ESR ohm
385	605	0.0002381	4200	0.172
220	800	0.0003571	2800	0.355

134	1025	0.0006250	1600	0.852
48	1712	0.0019341	517	6.425

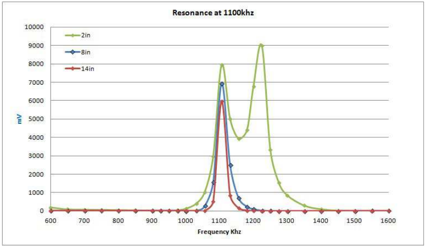
On the main plot then I have included for Ben's Cap B a second Q vs. ESR curve to illustrate the estimated benefit of using a higher tuning capacitance range. The new curve slides mostly to lower ESR (especially at the high end of the tuning range) and also to slightly lower Q. The improvements made appear modest from the modeled data and, for the case of a high-Q capacitor the possible improvements may be slight indeed. It is comforting to know that at least there should be no negative impact. Lower ESR certainly improves tank overall efficiency. This is a win-win situation where the set designer wins twice!

In seeking the "Holy Grail" tank capacitor I would add to the list of valuable features. We have ceramic stator supports, silver plating on the vanes, and good wiper contacts as features desired. I would add to this an extended tuning range if the capacitor is truly to be considered "Holy". With a standard 230 uH coil the tuning for the BCB ranges from 40 to 380 pF or so. With a 180 uH coil the capacitance needed ranges from 50 to 490 pF, (stray capacitance not accounted for).

Two questions immediately come to mind with this analysis:

1) To how low a coil inductance can you go?
2) If you find a few of these super-caps can you send me one?

kjs 6/2013 (in France)



A look at the resonance curves above (including an over-coupled 2-inch spacing case) is very interesting. I include this as a nice demonstration of resonance at various conditions of coupling. The 2-inch coupling case clearly demonstrates the problem of over-coupling in a radio. Two resonance peaks show up and tuning brings in different stations at the same time. Total power is still very high, just not useful. The 8-inch case is pretty close to critical with good power and the two-peak problem eliminated. Bandwith is still pretty high at 22khz (the curves are made with the 4 parallel HP's). Finally when separated to 14 inches the power loss is not too bad and bandwidth has narrowed to 10 giving a loaded Q of 107 as mentionned above.

It ain't Litz, but PD Close!
kjs 11/2012

tuggle tuner on this set is in the 50-80 ohm range giving an excellent match and maximum power transfer to the tank.

At the back end things get more complicated, a diode is present! For my testing I have included a step to determine, under test conditions of course, the optimum load resistance for maximum power transfer to the phones. Maximum power output means that the load resistance matches the output resistance of the tank/diode combination. The principal factors which influence this include the frequency and tank coil Q (which don't change from test to test), the diode Rd and characteristic, and the signal voltage being rectified.

Signal level and diode characteristic are inter-related and together determine the resistance of rectification. At very low signal voltages rectification takes place on the "square-law" portion of the diode with large swings in resistance with signal sine wave. Larger signal levels rectify higher on the characteristic curve (peak-detection region) with consequant lower resistances and less variation. The Rl shown on my table thus is specific for my test. My radio signal is in the 6-8 mV region placing it in the peak-detection portion of HP5082-2835 diode and possibly borderline square-law / peak detection on the FO-215. This explains why the optimum Rl is lower that of the HP but pretty close to the FO-215. It may also help explain why the FO bottomed out on the 14-inch separation, there was just no longer much signal for it to work with.

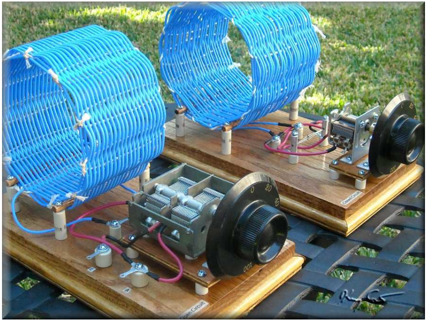
Dr. Gary L. Johnson, 2001. Lossy Capacitors
http://www.eece.ksu.edu/~gjohnson/tcchap3.pdf

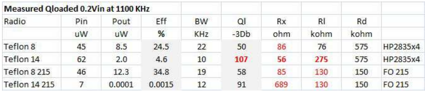
Pin = Power into the set in microwatts
Pout = Power out the back end (into the phones) also in microwatts
Eff = Set efficiency or Sensitivity and is the ratio on Pout to Pin * 100
BW = -3dB Bandwidth of the set at 1100khz (f res)
QL = Loaded Q of the set = f res / BW
Rx = Input resistance of the set in ohms
Rl = Load resistance on the tank in kohms
Rd = Junction resistance of the diode in the set

The power numbers are fairly straight forward and represent the power calculated across the dummy antenna resistor and load resitor. Input to the set is from a signal generator with a 200mVpp signal output. Losses due to the dummy were accounted for and the input power is that presented to the set itself. Looking at the Efficiency and QL numbers one sees nicely the tradoff between sensitivity and selectivity. The larger the spacing between the sets, the higher the QL, but at a sacrifice of sensitivity. While the numbers look low, they are still good for crystal sets and the 107 QL is a superlative number. By comparison, I have looked at a High-Performance built by Dave Schmarder (see my Radio Test page) with big Litz and super capicitors and this set max's out around QL = 120-125. I would opine that any QL above 100 is "Performance Quality".

Note for a bit the Rx numbers. Impedance matching for maximum power transfer starts at the antenna and antenna tuner. The dummy antenna used for the measurements mimics a fairly typical longwire with an output impedance between 25 and 50 ohms. Of the many radios I have measured, most have set input resistances between 100 and 250 or so ohms. The



Performance summary:



Measured Qloaded 0.2Vin at 1100 KHz									
Radio	Pin	Pout	Eff	BW	Ql	Rx	Rl	Rd	
	uW	uW	%	KHz	-3Db	ohm	kohm	kohm	
Teflon 8	45	8.5	24.5	22	50	86	76	575	HP2835x4
Teflon 14	62	2.0	4.6	10	**107**	**56**	**275**	575	HP2835x4
Teflon 8 215	46	12.3	34.8	19	58	85	130	150	FO 215
Teflon 14 215	7	0.0001	0.0015	12	91	689	130	150	FO 215

As mentionned at the start of the article, this set was designed as a high-performance rig. Lets take a look at the numbers and assess how well I did. On the spreadsheet above I have indicated the essential measures of the set in four configurations, two spacing tests (8 inches and 14 inches) with 4 parallel HP 5082-2835 diodes and two spacing tests with the holy grail FO-215 diode. First an explanation of the units:

Diode Modeling Update

Kevin Smith

http://www.lessmiths.com/~kjsmith/crystal/dmodel.shtml

The following explains my first attempt to compare a measured diode characteristics with calculated plots based on the Shockley Equation.

I have been taking serious look into diode modeling and measurement recently in an attempt to better understand these solid-state successors to the humble crystal and cat's whisker detector. There is much good information on diodes to be found in many excellent web sites of course, but there is nothing quite like actually making the measurements and working with them to get a good feel. This page reports some of my protocols and test setups which I have found to be useful.

Most probably the single best web article for the measurement of diode Is and n parameters is given by Ben Tongue in his Article 16. In this article he describes an interesting circuit for the measurement as well as protocols for making them. For my purposes I did not wish to make this a construction project and felt I might get along with good quality meters and my already-built "Diode Test Jig". Essentially Ben Tongue's method consists of making two precision measurements of Voltage and Current through a diode at small signal levels, essentially about 3 and 6 times Is (sufficiently low that the voltage drop across the series resistance Ro can be ignored). The measurements are then substituted into the Shockley equation Is*{exp[(qe/(n*k*T))*(V-I*Rs)]-1} and solved simultaneously for the two data pairs. Mike Tuggle has provided a nice excel spreadsheet to do the math. This spreadsheet, Cal_n_Is.xls forms the basis of my technique and

I am thus indebted to both Ben Tongue and Mike Tuggle for making this project feasible.

In addition to simply calculating the main parameters Is and n, I also wished to measure enough points to plot a characteristic curve, and to compare the measured curve with one calculated directly from the Shockley equation. My first spreadsheet then combined Tongue/Tuggle calculation protocol and a graphical view of the match between measured and theoretical. I did make a few methodology modifications which I thought/hoped would allow added accuracy:

1) Using the full Shockly equation without simplifying for an assumed 25dC room temperature. While the 25dC assumption is generally good and probably within the measurement error (or perhaps not), including the actual measured temperature eliminates doubts of inaccuracies due to this parameter. With the power of PC's and spreadsheets there is no reason simplify the equation.

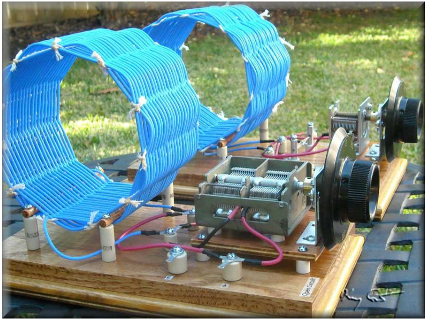
2) Used Vd = 0.04 and 0.05 V (adequately close to Ben Tongue's recommended 0.039 and 0.055 V) whenever possible. Note for some diodes with significantly different forward voltage drops, Si diodes in partictular I had to use higher values for Vd.

3) Reporting: I decided that, as there is no unique solution to n and Is, each is dependant on the valuse Vd and Id, I feel that reporting both Vd and Id is necessary for repeatability. Naturally I also include the ambient temperature in the report as well, and

4) I included a calculation for Ro (or Rg if you are using Tongue's reference) as that is the goal of the exercise.

from 4 to 7 or more khz off peak tuning when I remove my hand from the dial. The set is fairly modular and readily modified so I am keeping my eyes open for better quality caps. I am afraid I must learn to live with hand capacitance. Oh well, we see about the next set!

Portrait of set, ummmm..



With high-efficiency coils, very loose coupling is permitted with acceptable power levels, thus allowing very narrow bandwidths to be achieved. This can only be accomplished with separate base boards. To further minimize losses I have used short direct lengths of large 16 AWG stranded copper hookup wire and importantly, I have insulated all components and electrical connections from the board with ceramic standoffs. Finally, for the coils I have utilized a very lovely sky-blue teflon-insulated, silver plated wire of 18 AWG, strictly military spec, ($$$). I know, I KNOW.. This isn's a Litz Blitz set and yes, the performance suffers a little because of this. Still, I have good performance measures to tell me I am certainly on the right path. Note also that wire of such size and insulation is quite thick and to get the desired inductance required very large coils of some 4 3/4 inch diameter. The coils dominate the set visually and provide the name.

The tuning capacitors I would allow are most likely the weakeast link in the chain. I have chosen fairly generic though not bad-quality caps. The antenna tuner has a dual-gang cap with sections 465pF and 375pF respectively, well matched for my needs. Note, from my studies of antenna tuning (elsewhere on my pages) I have noted that a tuggle tuner does not necessarily require equal-size sections on the tuning cap. In fact, I would state that tracking is better if the ground section max's out at a lower capacitance that the tank section. The cap has aluminum blades and ceramic insulation and is a decent capacitor. For the tuning tank I chose a standard 410pF single gang unit from the Crystal Set Society. These are aluminum blade caps with phenolic insulation, OK but not superb. Both tank and atu include 3:1 reduction gears to help spread the band and allow more careful tuning. I did not allow for hand capacitance which I have noted is indeed a problem. When I tune the set to resonance with a signal generator, I find I am

To use the sheet one need only adjust the voltage Vd to that shown in the first column and record the current Id. If only Vd1/Vd2 and Id1/Id2 are measured then the next step is to adjust the value for "n" until the match between the two equations is exact. I even provided a simple ratio calculation to easily test for a match.

While the math is good and results excellent, I quickly found a couple deficiencies in my method,

1) measurements require high precision and its nearly impossible to land EXACTLY at the voltage required. I needed only to get quite close, let the meters stabilize for 2 - 5 minutes, and then record BOTH Vd and Id.

2) the work is rather tedious and, for a large number of diodes it pays dividends to measure only the needed Vd and Id and let the plot aside. My second spreadsheet thus dispenses with the plot. It is with my second spreadsheet that all my data tables and results are posted.

3) better comparisons between diodes can be made if one targets specific Currents rather than Voltages, discussion on this below.

A view of my current data reporting spreadsheet showing ALL input parameters as well as determined values of n, Is, and Rd.
Data input fields in blue: (target Id1 close to 1.0 uA and Id2 close to 0.5 uA).
Calculated fields in red and black.
Adjustment field "n" in green: (adjust value of n until the ratio of the two calculations = exactly 1).

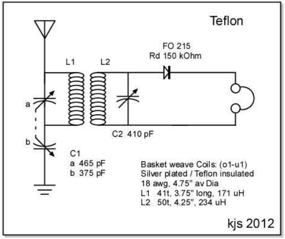
(Note: the engineers in the crowd will have noticed in the above report than I am carrying a degree of precision not justified by the level of accuracy in my measurements. The final results of n, Is, and Rd should be rounded off to not more than three significant figures.)
A copy of my spreadsheet can be downloaded here..

While measuring a good number of diodes, both Germanium, Schottky, Silicon, and even a few LED's, I noted that Tongue's recommended measurements at Vd = 0.039 and 0.055 V resulted in current reports spread out over more than two orders of magnitude. As the determination of Is and n is not unique but a function of Id, I felt uneasy by this method. While most Germanium diodes I have measured have a fairly narrow range of Forward Voltage drops, (Vf), that of Schottky's can range up to a tenth of a volt. This is the factor responsible for the huge range of measured Id values, see the following plot of I/V characteristics for some selected diodes:

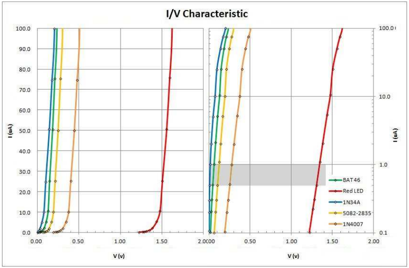
My Teflon Warrior

http://www.lessmiths.com/~kjsmith/crystal/teflon.shtml

With this current radio I am making my entry into the "Performance Radio" constructors club. I have tried to follow all the best practices of high-end crystal set design while giving the set my own personal breadboard mark. Two central themes guided my design on this set, simplicity and simplicity. From the circuit diagram below you will note that I have chosen, not surprisingly, a simple double-tuned circuit layout with a Tuggle front end and a Tank/Detector circuit with no circuit decorations whatsoever. No taps. No selectivity enhancement. No Benny. No Decoration. No nada. This is a basic radio wherein I have striven to keep losses, including insertion losses, to an absolute minimum. Should I wish to include selectivity enhancement and/or benny at a later time, they will go on an outboard platform along with transformer and phone plug. The radio itself is simplicity realized.



As can be seen in the set photos below, this design follows standard practice of placing the open and closed circuits of the set on separate baseboards. This is important as it allows easy and wide adjustment of the coupling between the coils.



In order to get what I feel is a better comparison between diodes, I have decided to target not some pre-determined voltage, but rather target currents of Id = 0.5 and 1.0 uA. On the above plot on the right (with Log Id vs Vd scale) it will be clear that I am aiming at the same part of the characteristic curve regardless of Vf. Hopefully this will allow good comparison between diodes with rather different Vf, even as far as including Silicon and LED's in my mix. On va voir....

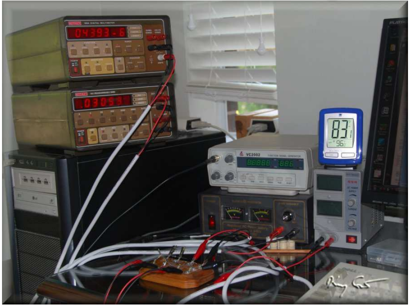
Shockley equation Id = Is*{exp[(qe/(n*k*T))*(V-I*Rs)]-1}
where:
n = ideality factor
Is = Saturation current in Amps
Id = Diode Current in Amps
Vd = Diode Voltage
k = boltzmann = 1.38E-23 J/K
T = temp K = 300
K = dC + 273.15 Kelvin
qe = electron charge = 1.609E-19 cmb

Often simplified to:
Id = Is*(exp(Vd/(0.0256789*n))-1) [at room temperature]

Diode Resistance Rd = VT * n / Is
Where:
T = 300K
VT = k*T/qe = 0.0256789
SO: Rd = k * T / qe * n / Is

I cannot express enough my indebtedness and thanks to Ben Tongue and Ken Khun for their great work and web documentation in matters Diode!

A photo of the current "bench" setup. Keithey 195A pico-ampmeter + Keithley 192 DMM bench meter.

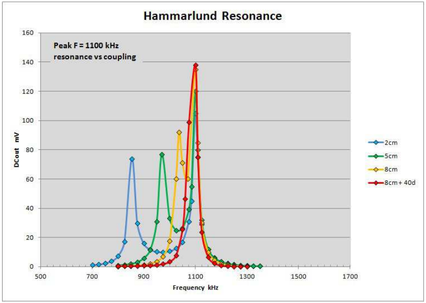


Kevin 09/2011

---

effects I can easily hear when tuning the set. Oh well.. Better be forewarned next time! This does not necessarily mean that double-tuned rigs MUST be built in modular fashion with separate tuning and detection units, but it certainly suggests it.
With the lack of surface real-estate to lengthen the coil separation, I made a small modification on the set as seen in the third photo above. There you see the possibility to rotate the outer coil away from vertical thus further lowering the coupling. I can get a max 40 degree rotation which just gets the coils to critical coupling. No more ghosts on the band! Still, I think my next double-tuned rig will indeed be modular. Experience is such a good teacher!

kjs 07/2011



A few words on resonance: When making my measurements I noted a curious effect in the resonance curves. They became increasingly asymmetrical with wider spacing of the coils and actually had a double hump at the maximum spacing of 10 cm. This is the exact opposite of how I expect resonance to work. I set to measuring the Vout across a significant portion of the MW band for each of the coil separations and present a graph below:

It should be readily apparent from the above graph that my set is badly over-coupled even at its widest separation of 10cm. I suspect critical coupling for the set is with a coil separation in the 15 - 20 cm range. Yet one more design consideration to keep in mind when making a new set! The double hump causes two problems for the set, one: it tunes each station twice and two: has the possibility to bring in two stations at the same time if they have the right separation on the band. Both these

Sensitivity on the other hand, well, it sucks. 2 to 11 percent Vdc/Vpp are very low numbers, many of my single tuned sets range from S = 10 to 50 and my Minstrel Boy getting over 60 percent. What happened? The data show the SEC to be involved here. Note that with capacitance in series the sensitivity is about 10% but when shunted across the tank the selectivity improves, but the sensitivity crashes down to 2-3%. I really expected better for this set. This is my second double-tuned rig, my first was a simple set using solid magnet wire close-wound on 3" cardboard cores and having 6 twisted taps, all Q lowering. This sets' coils have no taps and no cores and ought to have significantly better Q. The primary difference between the two sets is the presence of the benny and SEC on my new set. I am worrying about insertion losses more than offsetting the improvements in the coils.

The severe loss of sensitivity when using the SEC on this set also reminds me of my experience with my Fleming set, a modified MRL#2 using SEC. There I also found loss of sensitivity when the SEC was in the circuit. At the time I concluded that the circuit was inappropriate for testing the SEC concept, now I am not so sure. This set employs a high-performance circuit (if not high-performance parts) and is fully correct for the SEC inclusion. One additional test I intend to make when time allows is to completely remove the SEC and Benny ornamentation from the set and re-test the sensitivity. I suspect that insertion losses are killing me. Dave Schmarder has the most experience with this design feature, I wonder what his thoughts are? Have you tested a set with and without the SEC? What have you found? I am suspicious of this feature now.

capacitor which places the capacitance either 1) in series with the top of the tank and detector, or 2) shunted parallel across the tank. I make a full set of measurements with the SEC cap set fully to each the series and shunt positions. The above paired measurements are made for each of three coil coupling positions. The two coils can be shifted along two rails to bring them from essentially touching to a maximum separation of about 10 cm, or about one coil diameter. This is the max separation obtainable on my breadboard as the Hammarlund caps are quite large and take up much space. To evaluate the impact of coupling, I measured with the coils separated 1cm, 5cm and the max 10cm.

OK, enough with the preliminaries let's look at the data!

	1 cm		5 cm		10 cm		
SEC	series	shunt	series	shunt	series	shunt	
Res	214	46.2	209	51.7	217	52.6	mV
BW	16	14	17	11	18	13	kHz
Q	68	81	66	100	63	87	
S	11%	2%	10%	3%	11%	3%	Vdc/Vpp

The table at left presents the measurements (Res = resonant peak Vout mV : BW = bandwidth and -3dB : Q = under load : S = sensitivity = Vdc/Vpp) vertically and the different cases horizontally. Bandwidths for the cases all range between 16 - 18 kHz for SEC in series and 11 - 14 kHz for SEC in shunt. These are pretty good numbers for a standard (non-DX Contest) rig and correspond to Ql in the 65 - 85 range. Context for this comes from Ken Khun's excellent engineering pages where he notes for crystal sets that loaded Q normally ranges between 10 (poor) to 50 (typical) to 100 (very good). My set here then is pretty good in this respect and confirms my eardrum assessment above.

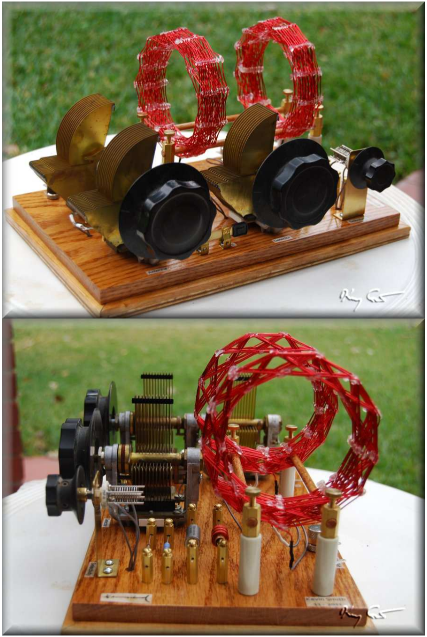
A few words of the performance of my Hammerlund set are in order. When I first started using the set I noted with satisfaction that, by my eardrum meter, the set seemed to indeed tune quite sharply. This is certainly my principal goal in making this double-tuned set. The only fly in the ointment was that the radio seemed quite insensitive, the stations coming in very weakly and needing amplification. The SEC control did have an interesting and dramatic effect when used, but it also hugely lowered an overall low sensitive set. With these thoughts in mind, I have spent some time making some preliminary measurements on the sets' resonance, sensitivity and selectivity.

To characterize the set completely, I measure under a number of different cases. I wish to test the effect of the selectivity enhancement circuit (SEC). The SEC uses a 20pF differential

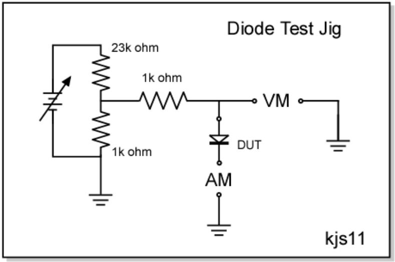


Diode Test

Kevin Smith

http://www.lessmiths.com/~kjsmith/crystal/dtest.shtml

So, what is the best diode out there to use? Do crystals always show poor sensitivity compared to germanium? What about Fleming's marvelous device, the vacuum diode? I start by using a test jig, the design shamelessly modified from Dan Petersen in the Nov 2009 Crystal Set Society Newsletter, (if you aren't a member, go sign up to be.. NOW):



This is a very simple circuit allowing power input, attaching a diode for testing, and sampling both the curent and voltage across the diode under test, (DUT). I made a simple modification by adding a voltage divider, about 20:1 at the power input. The power supply can be connected either at the front across the divider, or after the divider in front of the 100k current limiting resistor for higher voltage readings. I get the input voltage from a modest 18V, 2A regulated DC power supply. This unit has both volt and amp controls with digital readouts, nice to use and dosnt take up much room on my desk. Here is a case where I recommend you look at getting a new unit. I looked long and hard on ebay, but found few bargins and few units with the same features. Still, the supply regulator was never designed to adjust the output to precise small values making it somewhat difficult/tedious to adjust. Adding a small rheostat to the test jig may aid for making fine adjustments on the voltage. Another piece of equipment you will need for this test is an amp meter. I use a nice small digital meter I found new on ebay for $15 shipping included. It reads amps to a lowest range of 200uA, more than enough precision for the task. For that price get two. The DVM is, of course, my trusty Keithley workhorse. Easy protocol as follows:

1) Set up the test with the diode and meters clipped to the jig.

2) Adjust the power supply until the reading on the DVM meter is where you plan to measure. Adjust the voltage (DVM readout) in steps from 0 to 1.0 Volt in 0.1 V increments and record the current (Amps) in a spreadsheet.

3) Repeat at each tenth volt recording while the spreadsheet makes a sweet graph.

Test Results

First, I offer a quick look at my diode modeling setup. I am currently upping the ante on resolution in order to determine diode parameters Is and n, hoping for success soon! Setup and protocol..

Over a period of a few weeks I ran I-V characterization tests on a good number and variety of diodes, crystals and my two tubes to see how very thing stacks up. The following presents the resulting curves, diode photos, and some puzzling questions/conclusions I churned up in the process. I start off with the realization that when one orders diodes, it is by no

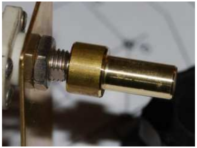
Something was needed here! At left is a photo of a very sweet brass shaft converter machined by my clever and capable EE elder brother, many beaucoup thanks for your addition to the project! Not being an engineer myself I was able to follow very poor practice and just wired the whole lot together, crossed my fingers and hooked the sucker up.. Ya Hey! There be sounds here!

The set is playing as I type these words and I am most hopeful for a successful performance goal. Although much testing and measuring yet remains to be done, the set by ear calibration tunes quite sharply. The coils have 4.2 inch OD and 3.2 inch ID and can slide upwards of 4-5 inches separation for looser coupling. The selectivity control has a dramatic effect on sensitivity and, I am sure, on selectivity as well.. to be measured soon so stay tuned.

The photos below present the set in its final functionning form.

tried this before on a version of an MRL-2 but it was a disappointment, not the right set for the test. As this set was to employ a high-performance circuit, an SEC would be appropriate. The set itself is only moderate performance though, the caps having fairly high-loss brass plates and my coils wound with solid wire. This set also ploughs new ground for me in my first basketweave coils. Basketweave coils recuce stray capacitance and increase coil Q by eliminating the need for lossy coil formers. As these were my first, I merely used solid wire I had in the house. As they are wound of 20awg solid wire, they are quite springy and I had to hot-glue the bejeezes out of them to get them to stay put. I do one day expect to build a truly hi-performance set, but this is just a stepping stone to test components and design. As such, I tossed a benny into the circuit for good measure.

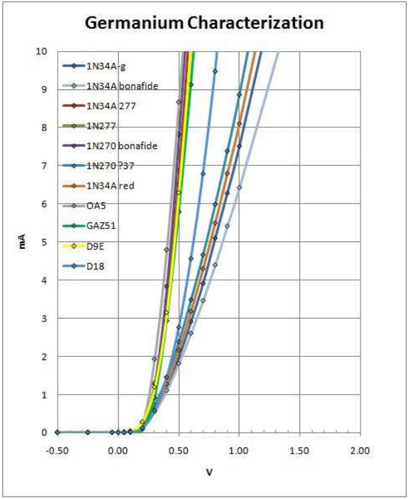
The design calls for non-tapped coils to increase coil Q. While the coil Q is not great, it is certainly considerably better than any of my earlier cardboard tube or even PVC selonoids and it ought to have a decent tank parallel resistance. Matching (hopefully) to this I used a germanium FO-215 diode from Mike Peebles. The combination in these diodes of low n (~1.1) and Is (190) gives a diode with moderately high junction resistance on the order of 150+ kOhm which should work well with the solid-wire coils in the tank.



The selectivity enhancement circuit called for a cool 20pF differential cap which I found at Surplus Sales of Nebraska. The cap itself is a cute little item but the shaft was a short 1/4in long and only 0.19in in diameter.

means certain what one will get. This seems especially true for the supposedly ubiquitous 1N34A. Unless you see the part number actually on the diode, you probably need to test it to know what it really is. So, lets take a look!

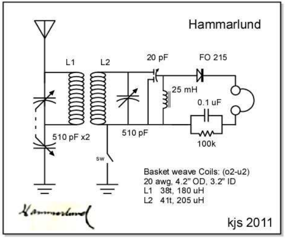
Germanium Diodes



Hammarlund, Double-Tuned

http://www.lessmiths.com/~kjsmith/crystal/ham.shtml

This fine radio features three beautiful and high-quality Hammarlund square-law 510pF variable capacitors. I have been hankering for some time to build a radio with more than just OK to mediocre performance, which translates to a double-tuned set with a properly tuned front end. The capacitors mentioned before were, at first, a poor choice for this project as I needed for the antenna tuner a two-ganged variable cap and the Hammarlund units were only single. Additionally, I only had one! With what I can only call considerable luck, two additional identical capacitors were listed over the last several months on ebay giving me three total. The caps are high quality and very heavy construction and I figured I ought to be able to dismantle them enough to give a common shaft to two thus ganging them as needed. This turned out to be the case and the project was a go.



Additionally, with each radio I build, I like to test and learn new circuit concepts and ideas. This radio was to be made with a farily simple double-tuned circuit, a tuggle-tuned front end and variable coupling. I also wished to test and play with the "Hobbydyne" or selectivity enhancement ideas presented by Dave Schmarder on his excellent site. I had

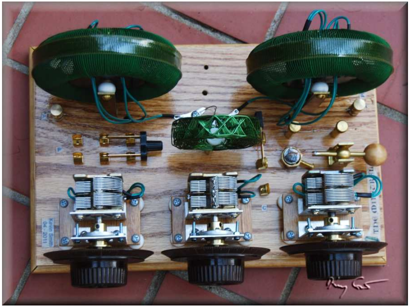
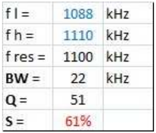
When I did get around to hooking the set up to the signal generator I found to my relief that indeed the set has good (not great) selectivity and really excellent sensitivity. Bandwidth around a nominal 1100KHz signal to -3dB is 22KHz giving this set a loaded Q of 51. This is right in the middle range of set loaded Q to be expected for a "typical" crystal set given by Kenneth Khun in his notes on Resonant Circuits. Importantly as well, this set does a much better job at rejecting KGOW than my other sets. I attribute this to the main coils being toroids. KGOW blasts down my direction with a very powerful ground wave and I suspect that the other set coils, mostly open selenoids and / or spiderweb, are picking up the signal and flooding my set across the tuning range. Toroid coils confine the magnetic fields within the torus and thus couple poorly if at all to surrounding fields, including KGOW. Thank you Magnavox for making such lovely coils!!

View from above.





f l =	1088	kHz
f h =	1110	kHz
f res =	1100	kHz
BW =	22	kHz
Q =	51	
S =	61%	

Performance summary for the set is quite pleasing. When I first started listening to the radio I immediately got the sinking feeling that the selectivity would be no better then many of my earlier sets, a disappointing prospect especially as this set was meant to be a higher performer. Part of the problem what just the sets' general quirky and difficult three-dial tuning method. I soon got used to fiddling with the dials and found I could usually "tune out" most any nearby or interfering station from the one of interest, it just took some effort.

Here we see a set of Germanium diodes and photos of the diodes under test. Immediately you should notice two sets of curves, what I call the "1N34A" set and the "1N270-277" set. In this analysis, the second set appears clearly superior in sensitivity and deservedly so. In the photos it is clear that one bunch of diodes I purchased as 1N34A were in fact better 1N277, the black band and thin gold contact wire as well as common curve unite these. "True" 1N34A's have a more robust contact wire. I also purchased a 1N270 and received pretty orange diodes with the number "37" stamped on it, a fairly robust contact wire and a curve that most closely resembles a 1N34A, go figure. Mercifully, I DID manage to get some bona-fide 1N34A's with the part number on the diode, as well as a single bona-fide ITT 1N270 diode with the part number. These are my base for comarison.

In addition to the standard Germanium Diodes tested above, I also have latched my hands on a few "other" germanium diodes for the fun of testing. These include two vintage Russian types, a D9E (in the 270 class) and a D18 (transitional between 270 and 1N34A). Additionally, I got a few FUZZ diodes popular, I suspect, with the guitar gadget crowd. These are larger packages in metal cases so I cannot see how the internal contact is made other that they are stated to be gold bonded point contact type. Clearly these are highly sensitive diodes in my 270 class, the OA5 looking best of the lot. Interestingly, I recently purchased from good Mr. Peebles a few of his "Holy Grail" ITT FO-215 diodes. My measured characteristic for one of these is a dead laydown on the gold-bonded OA5. From the photos, these are in different packaging with the FO-215 in a traditional glass casing. What makes the FO-215 so great is the fact that its resistance Rd is an interesting 150k ohm or so which matches very well with typical moderate Q tank curcuits. Interestingly, I find that an old Russian D18 diode has very similar characteristics to the FO-215 and so much also be placed into the "Holy Grail" class of germanium diode. Take your pick!

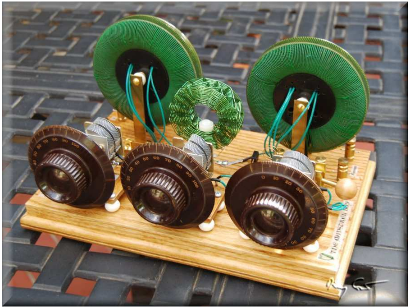
Averages: n = 1.38 Is = 1315 nA Rd = 52 kOhm

The above spreadsheet is based on measurements of the diodes shown above. For the determination of Is and n, I chose at random two examples from my collection of various diodes, (all germanium in this case) and measured via a modified version of the methodology outlined by Ben Tongue and Mike

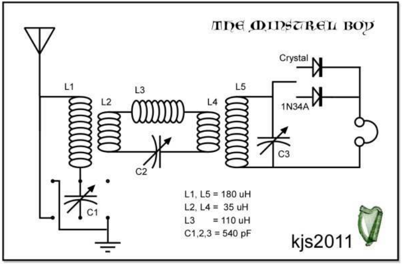
Unfortunately the primaries do not have taps. 180 uH is a bit low for MW work and would require a variable cap with a fairly high top end. I chose three identical 2-gang 270 pF caps tied in parallel to give three 20 - 540 pF tuning. The link circuit consists of two serial 35 pF secondaries for a total of 70 pF, not enough to tune with so I would need to add further inductance. Here is another new feature for me. I made for this set my first honeycomb-style coil, green, of course. I gave the link coil 110 uH for a total link inductance of 180 uH, just as in the primaries. All tune with the three variable caps. Additionally I added a series-parallel knife switch for the antenna circuit capacitance. For my setup the series position will work best, but this will add utility later on. (One green feature I tested and subsequently abandoned was a green LED diode, but even with bias I found it to be hopelessly insensitive).



Portrait of set, Wearin O'the Green..

sharpen the tuning overall. This method forms a triple-tuned set with its consequent quirkiness and occasionaly annoying tuning. Still, I find this part of the fun, I am not looking for tuning efficiency, just sharpness.

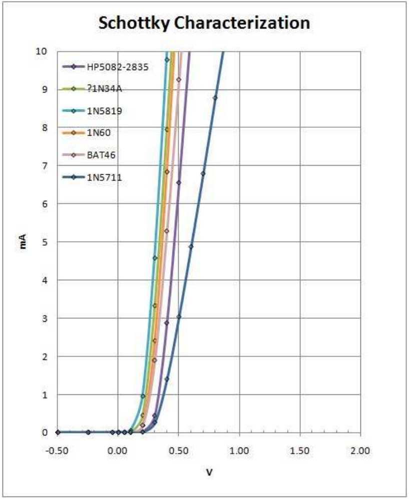
The lovely green color and large size of the coils would be a prominant design feature and this immediately suggested an Irish theme for the set. I settled on naming it "The Minstrel Boy" from a patriotic Irish song written by Thomas Moore, reproduced at the bottom of this page. Of course the name also reflects the idea that I expect to listen to music on the set, it will be a minstrel for me. This decision then set in motion the need for other green features, green hookup wire and making a link coil from green magnet wire. Finally a 1N34A diode I bought a couple years back from Dave Schmarder with the green band to cap things off.



The toroid coils have identical features including a primary with 180 uH and a secondary coupling coil with 35 uH.

Tuggle. For this work I have chosen to set Id2 about 0.5uA and Id1 about 1.0uA and then read the needed voltage. This is the inverse of the normal method but the justification is that for any diode regardless of forward voltage drop the measurement is made at the same part of the LOG I vs V characteristic. This allows comparison between all diodes. I have included the actual room temperature in the calculations in order to eliminate this variable as a source of doubt or error. All the measured parameters as well as the determined results are presented in order to facilitate repeatability.

Schottky Diodes



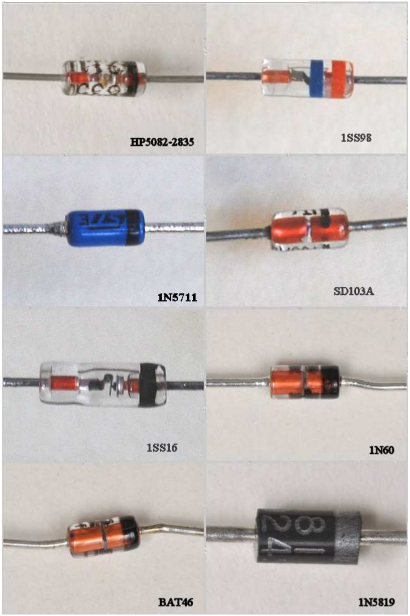
The Minstrel Boy, my triple-tuned triple-threat!

http://www.lessmiths.com/~kjsmith/crystal/minstrel.shtml

I am always on the lookout to find interesting and different circuits with which to construct my radio projects. About a year or more ago I found on ebay an interesting deal for a set of three vintage toroid Magnavox (Model D) air-core coils. They are wound from a beautiful lime-green cloth-covered wire and I just had to make an effort. I assumed, correctly as it turns out but not obvious from the description, that they would come with internal coupling coils. I also assumed they would have a tap somewhere on the main coil but in this I was to be disappointed. I was also disappointed to discover that in one of the three coils the secondary connection was broken. Oh well, my project needed only two coils and I knew these would make a fine radio. I already had a link-coupled design in mind.

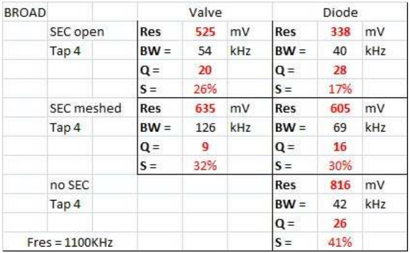
Toroid coils are interesting in that they confine the magnetic field within the center axis of the toroid. Because of this, stray coupling seldomely causes a problem, but then again, coupling in general is not easy. So, I had the idea these would be my ticket to exploring designs with capacitive or link couplings between circuits. Eventually I began scouring the net and my books/references for circuits employing link coupling. This coupling method seems to come in two main varieties, tuned (such as found in the Crystal Set Societys' "My Marconi" set), and untuned (as found say in MRL's #42 set). Tuning the link is not needed, but it was something I wanted in an effort to virtually no difference between the Narrow and Broad performance. Oh well... At least I understand now why Osterhoudt removed the choke from the MRL#2 set.

Q for this single-tuned radio is comparable to other radios I have built. This is a circuit demonstration radio presenting Fleming's valve. Nor have I finished with the SEC concept. The circuit utilized here is not ideal for the SEC, ground is taken off the top of the coil, its an odd, if interesting, configuration. I will give the SEC another shot with some other radio. Overall, I am very pleased with the set and enjoy listening to the local Spanish music format station with the warm glow of the tube keeping me company. Oh that glow....



Schottky diodes are very sensitive diodes that work excellently in crystal radios. Their construction and theory are different and I confess to not fully understanding these components. Still, from the characteristic curves, they are excellent! Again, note that you dont always get what you bargain for. Here I found what was supposed to be 1N34A's to be some sort of Schottky of unknown pedigree. The 1N5819, while having the lowest forward voltage drop, has a rather very high Junction Capacitance and will not perform well. Posts on the RaidoBoard Crystal Radio Forum however highly recommend the 1N5711 for crystal sets although the characteristic curve dosnt look that fabulous. Many web pages out there on Shottky diodes, I recommend you do your homework. Of all the schottky's, I note that Ben Tongue recommends most highly the HP5083-2835. The high resistance Rd makes them useful for DX sets with very very high Q tanks. Even so the diodes need to be paralleled with up to 4 or 5 diodes to match correctly the Rd with the tank Rp. I have found these somewhat hard to find and expensive, especially when one requires using several in parallel. I recently measured a few 1SS98 diodes and I discover them to have characteristics extermely similar to the HP and I feel they deseve more attention. Sadly, on ebay they seem to be just as difficult to find and expensive. No free ride!

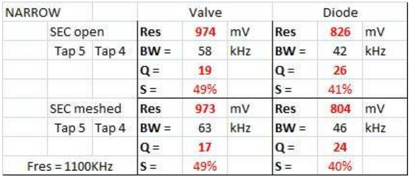
Spreadsheet below for calculation of Schottky diode n and Is (modified from Mike Tuggle's spreadsheet)



BROAD		Valve			Diode		
	SEC open	Res	525	mV	Res	338	mV
	Tap 4	BW =	54	kHz	BW =	40	kHz
		Q =	20		Q =	28	
		S =	26%		S =	17%	
	SEC meshed	Res	635	mV	Res	605	mV
	Tap 4	BW =	126	kHz	BW =	69	kHz
		Q =	9		Q =	16	
		S =	32%		S =	30%	
	no SEC				Res	816	mV
	Tap 4				BW =	42	kHz
					Q =	26	
Fres = 1100KHz					S =	41%	

Looking at the performance in the Broad setting we find the SEC has a definite impact. As before, the valve has higher sensitivity than the diode, but here we see a classic tradeoff between sensitivity and selectivity. Turning the SEC to its maximum selective position (lowest capacitance) helps, (Q increases from 9 to 20 with the valve) but at the price of lower sensitivity, (Decrease from 32% to 26%). More disturbingly, the overall sensitivity in the broad setting, which ought to be higher than in the narrow setting, (that is, greater than 40%) is quite the opposite, (less than 30%). Additionally, setting the SEC to its most selective position merely returns the radio to a selectivity already found in the narrow setting (narrow Q = 18, broad Q = 20) while lowering the sensitivity. So, I consider the SEC in this circuit a bit of a failure. My suspicion is that the insertion losses associated with the SEC are damaging and no real selectivity boost is given that was not already found in the narrow setting. To address this, I removed the choke and minimized the capacitance of the SEC, effectively removing it from the radio. Re-testing the radio now showed a return to good sensitivity and moderate Q. Actually, with this test I see

(Russian D9E, a 1N270 equivalent) and the tube/valve (Russian 6C19P) in place.



NARROW			Valve			Diode		
	SEC open		Res	974	mV	Res	826	mV
	Tap 5	Tap 4	BW =	58	kHz	BW =	42	kHz
			Q =	19		Q =	26	
			S =	49%		S =	41%	
	SEC meshed		Res	973	mV	Res	804	mV
	Tap 5	Tap 4	BW =	63	kHz	BW =	46	kHz
			Q =	17		Q =	24	
Fres = 1100KHz			S =	49%		S =	40%	

Looking first at the radio in the Narrow switch setting. The table at left indicates the peak output DC signal in mV at resonance, the measured bandwidth at -3dB above and below resonance, calculated radio Q and Sensitivity (Sensitivity here is simply 100 * DCout / ACin). The table shows that the SEC circuit itself provides no change in performance. This is expected as noted above, the SEC doesn't impact the circuit in the narrow setting. I ran the valve at 6.3 V on the heater filament and am surprised to see that the radio sensitivity is higher with the valve than with a diode. Dissappointingly, the valve had a poor effect on the radio Q, going from Q = 25 with the diode to Q = 18 with the valve. I have to imagine the valve has a rather different impedance / capacitance characteristic from the diode. Still, the good sensitivity is pleasing to see.

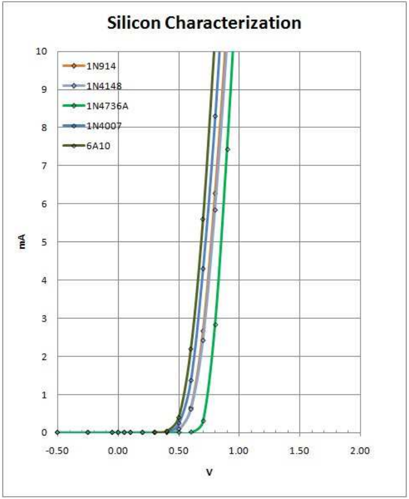
Averages: n = 1.48 Is = 1275 nA Rd = 1030 kOhm

The above spreadsheet is based on measurements of the diodes shown above. For the determination of Is and n, I chose at random two examples from my collection of various diodes, (all schottky in this case) and measured via a modified version of the methodology outlined by Ben Tongue and Mike Tuggle. For this work I have chosen to set Id2 about 0.5uA and Id1 about 1.0uA and then read the needed voltage. This is the inverse of the normal method but the justification is that for any diode regardless of forward voltage drop the measurement is made at the same part of the LOG I vs V characteristic. This allows comparison between all diodes. I have included the actual room temperature in the calculations in order to eliminate this variable as a source of doubt or error. All the measured parameters as well as the determined results are presented in order to facilitate repeatability.

Silicon Diodes



The glow.... Oh the glow!

PERFORMANCE:

So, is is a keeper? Does it perform well? Is Fleming's valve a revolution? The following tests answer all these questions and them some. We start by noting from the circuit diagram above that this is essentially two radios depending on whether it is switched in the Narrow or the Broad setting. Importantly, in the narrow position the SEC option is essentially out of the circuit. This will be seen in the measurements as well. A note here, all measurements were made at a nominal 1100KHz with a signal generator and the output of the generator was a sine wave with 2.0V p-p. This is a strong signal and may impact the results, especially concerning sensitivity, but it makes for easier measurements and ready comparison between sets. For this set I made identical measurements with both the diode

Averages: n = 1.52 Is = 2 nA Rd = 2.4E8 kOhm

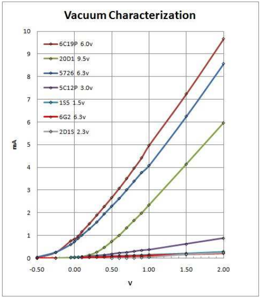
The above spreadsheet is based on measurements of the diodes shown above. For the determination of Is and n, I chose at random two examples from my collection of various diodes, (all silicon in this case) and measured with a modified methodology to that outlined by Ben Tongue and Mike Tuggle. In this case, with the radically different forward voltage drop of these diodes from Germanium or Schottky diodes, I have kept the Id values constant (about Id2=0.5uA and Id1=1.0uA) and varied Vd. I have included the actual room temperature in the calculations in order to eliminate this variable as a source of doubt or error. All the measured parameters as well as the determined results are presented in order to facilitate repeatability.

Additionally I purchased a small variety of tubes for testing. The results of this study are discussed in full under the Radio Lab : Diode Test section of my page. Of all the tubes tested, I finally chose the Russian 6C19P as the tube having the most sensitive characteristic and a handsome appearnce. The tube is a power-hungry beast though, (1.1 Amp current draw at its rated 6.3 V), and this radio requires a power supply, but its worth it! The following graph plots the characteristics of seven tubes I tested for the project.

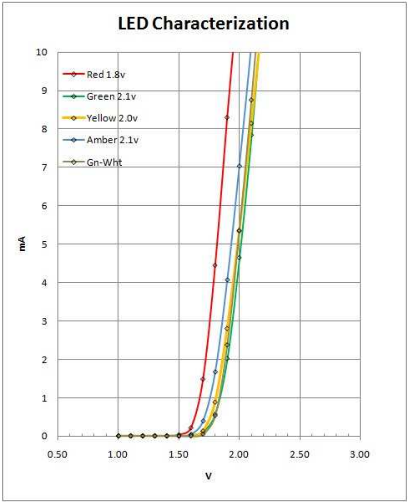
While the project radio was to feature the Fleming valve, I naturally wish to have an interesting circuit as well. As always, it would be a breadboard set and single tuned for ease of use. I also wished to utilize and test Dave Schmarder's selectivity enhancement circuit (SEC) in the set. This last item to compensate for the typical poor selectivity in single-tuned circuits. One circuit that caught my eye from an early time was Modern Radio Labs' MRL#2 set. To this set I would add the SEC modification. In such configuration I notice that it bears a remarkably close resemblance to Set #6 in W.J. Mays' Boys Book of Crystal Sets (BBCS). The MRL#8 set also shows design affinities and includes the choke missing in MRL#2, a fact noted by Mr. Osterhoudt himself. In the end my circuit design, shown below, must be considered a close, (but not exact), member of a family of radio circuits consisting of MRL#2, MRL#8, and BBCS#6.

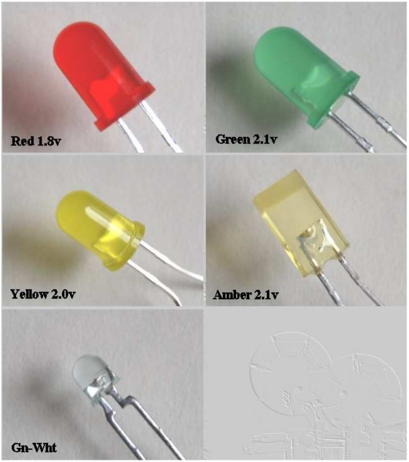
Most avenues of research proved futile until he recalled his prior work on the Edison Effect. He literally retrieved the original bulbs he had experimented on previously and set up a test to apply the effect for radio wave rectification. His experiments were certainly successful. This idea proved a novel and unanticipated use of a prior-known effect amounting to true discovery and thus was awarded British (24,850) and American (803,684) patents in 1905, these successfully defended against De Forest's subsequent infringements. Pondering this interesting history, I began wondering about the Fleming diode and thinking, in crystal radio, this is not amplification, so why not? Also, one must consider the glow, oh the glow… I just had to build this.

Finding a correct tube for the project is a bit of a story in itself. I have never worked with tubes and, while it appeared natural that diode tubes ought to exist as well as triode/pentode/etc (they do), I had no idea what tube was what nor how to know what would work for radio rectification. Many diode tubes I found are for power supply work and may not be appropriate for radio detection at all, (actually they work fine). Jumping into the search both feet, I waded through the datasheets of many/most diode tubes to get to know them well enough to choose.



Light Emitting Diodes



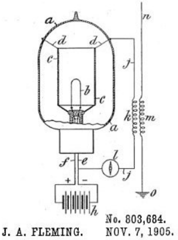


As long as I am measuring various and sundry diodes, I figure I ought to include that most ubiquitous of modern diode, the LED. Found everywhere, these diodes are rapidly becoming the low-energy light source of choice for many lighting applications. I have read occasionally of someone asking whether these ought to be useful for radio applications as well. To this question the answer is generally a resounding "No!". The turn-on voltage is waaay above any reasonable value

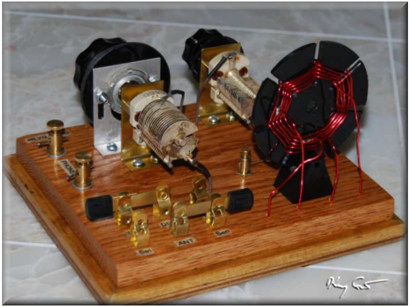
Powered by Fleming's amazing valve

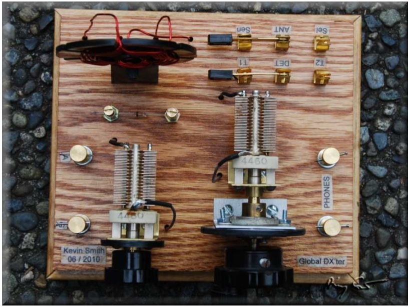
http://www.lessmiths.com/~kjsmith/crystal/flm.shtml

Crystal radio circuits come in a seemingly endless variety of forms and possibilities. That and the historical context of their importance at the dawn of the radio-age makes them a fascinating hobby. I enjoy making these radios, learning and exploring new and interesting circuit ideas, incorporating vintage components into my sets, and finding historical connections between the radios and the fathers of the technology.



My latest project involves a passive receiver rectifying the signals with a vacuum diode. Professor John Ambrose Fleming had consulted for Edison Electric in Britain and had experimented extensively with Edison two-electrode bulbs in the 1880's, presenting his results on the "Edison Effect" to the Royal Society of London in 1889, and the Royal Institution in early 1890, and finally his definitive paper to the Physical Society of London in 1896. Later after the turn of the century he began consulting for Marconi seeking better mechanisms for radiotelegraphic detection of radio signals.





expected to be delivered by an antenna to a crystal set. Still, this simple answer avoids the actual question, what in fact does the characteristic curve of a LED really look like? Where is the turn-on voltage with respect to the published junction voltage, (assuming you can find that).

To provide just such a look I visited my local electronics store and bought a small handful of LED's, most with the junction voltage listed and took them home to measure. Typical LED junction voltages seem to range from about 1.8v to 2.1v or more. The turn-on voltages look closer to 1.6v-1.7v. Anyone used to working with Carborundum crystals or silicon diodes will be used to biasing their rectifier to get good sensitivity. These LED's once on have a very sharp rise and with a proper bias should work quite well as detector diodes. As a bonus you will get a sweet glow as well. OK, not as cool as the glow of a vacuum diode, but certainly more sensitive!

Averages: n = 2.01 Is = Tr nA Rd = 3.8E19 kOhm

The above spreadsheet is based on measurements of the diodes shown above. For the determination of Is and n, I chose at random two examples from my collection of various diodes, (all led's in this case) and measured with a modified methodology to that outlined by Ben Tongue and Mike Tuggle. In this case, with the radically different forward voltage drop of these diodes from Germanium or Schottky diodes, I have kept the Id values constant (about Id2=0.5uA and Id1=1.0uA) and varied Vd. I have included the actual room temperature in the calculations in order to eliminate this variable as a source of doubt or error. All the measured parameters as well as the determined results are presented in order to facilitate repeatability.

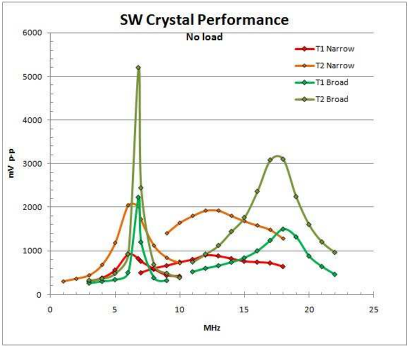
Why know the values of Is, n, and Rd of your diodes?

I have been attempting to get a handle on the main diode parameters Is, n, and Rd and how they impact the operation of a crystal radio. My method of choice is to use a graphical approach, plotting charts where variations between plotted parameters become apparent and easy to visualize. I have developed an interesting chart from the measurements above that compares many diodes with respect to Is, n, and Rd, and to understand how this fits into a matching situation with a fuzzy indication of typical tank impedance limits.

Ultimately one seeks a diode with an Rd that matches with and conjugate to the impedance it sees from the tank (+antenna). In the following discussions I will start with the cross-plot of Is to Rd and then proceed to a look at how received RF power plays a part in the selection and why low Is and n are desired.

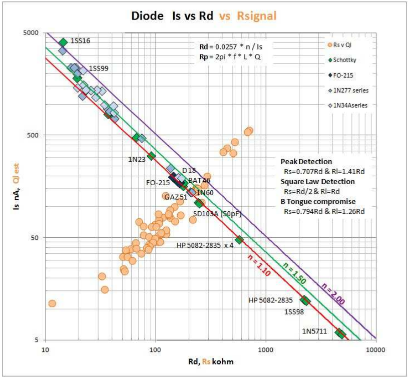
What I found then, was a farily sensitive but, to be truthful, woefully selective set tuning from 6 to about 17-18 MHz. Not bad for a single-tuned rig.

Final thoughts. Upon returning to my home base, I quickly hooked the set to my longwire to make first impressions of actual reception. In midday I was able to pick up a spanish language format broadcast and two english language religous format stations and a brief encounter with WWV. At night the bands are flooded with competing stations, success! Note that all this with my handy dandy Radio Shack mini-amplifier. When I connected a crystal earphone and used my poor hearing, there was nothing as expected. One pity is the ongoing presence, even on this set, of KGOW 1.65MHz forever audible in the background. I consider the set a success as I was not expecting selectivity in a single-tuned rig. Still, with the bands dominated by religous and spanish broadcasts, I cant say it differs much from the local Houston AM fare. Oh well...



The plot above charts the received signal strength (p-p mV) versus input frequency for the four possible switch configurations (Detector on tap 1 or 2, Antenna on selective [top of coil] or broad [on tap t1]. These four conditions were tested with the tuning cap fully meshed (low frequency) and fully open (high frequency) to give an idea of the actual tuning range as compared to the calculated range. All measurements were made with no load on the output, and the antenna trim cap in the full meshed position. Other conditions not shown were also tested.

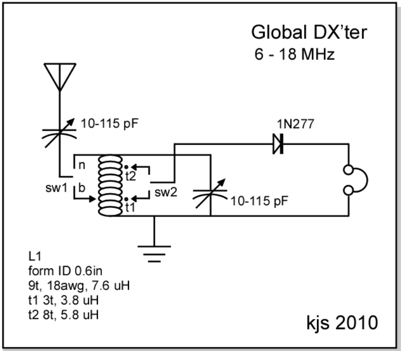
The results indicate that placing the antenna low on the coil, on the T1 position gives the best sensitivity and selectivity in tuning. The detector, a 1N277 germanium diode placed high on the coil at T2 also gives dramatic increase in sensitivity.



The plot above shows the relationship between diode Is and Rd. Rd is calculated via the equation Rd = VT * n / Is where VT is the thermal voltage = k * T / q = 0.0257V at room temperature and Is and n are from the measured diodes. k is Boltzmann's constant = 1.38E-23 J/K and q is the electron charge = 1.609E-19 coulombs. On such a plot I can show lines of constant n, and plot the values for individual diodes for which I have spent considerable effort to determine the parameters Is, n and Rd (where Is is the diode saturation current, n is the ideality factor, and Rd is the diode resistance). On the plot it should be evident how changes in n or Is impact a diodes' Rd.

Additionally I have plotted RF signal Rs as orange circles from published coil unloaded Q (see my section on Coil Q). To convert from Qu to Ql I have made the assumption that loaded Q is about 1/5 unloaded Q for low-end sets while in performance sets it may approach 1/2.5 the unloaded Q. This is only an estimate then, but starting from actual data. To make the conversion to Rs I simply plugged the data into the standard equation R = 2pi*f*L*Q using a scaling factor to divide down Qu to Ql from high Q (1400/2.5) to low Q (100/5). This provides a nice visual display of the expected range for Rs in many crystal sets. I plot the Rs against the value of Ql used. Note that these data are for the case at about 1MHz and inductances between 200 and 300uH, as published.

Matching the diode to the tank is a matter of finding a diode with both sensitive qualities (low n) and an Rd close to the Rs presented to the diode (as per Ben Tongue's suggestions for Peak and Square Law detection). Those diodes with Is's in the 100 - 250 nA (100-280 kohm for n=1.1) or so range have the possibility to match while connected to the top of the tank coil without the use of Q-lowering taps, while untapped matching to high-end high-performance big-Litz baskets will require diodes with Is's in the 35 - 60 nA (500-800 kohm for n=1.1) range. Most "typical" germanium diodes have high Is values (>500, >60kohm) and will require a tap. Diodes such as FO-215, BAT 46, 1N60 and GAZ51 can be matched to many tanks without taps. For tanks with high quality Litz coils one will be using HP 5082-2835 or 1SS98 diodes, generally 3 to 4 in parallel to lower the Rd to the desired range. (Curiously, I have not found any diodes with Rd values in the 300 to 4500 kohm range.) Note that both resistance and impedance are frequency-specific so a match at one frequency will not remain matched across the broadcast band.



Initial testing on the set was dismal. NO RECEPTION. There followed many hours of double checking all wireing, solder joints, fidelity to the schematic, etc. Everything checked out, no good. Time to seek professional help, which happily corresponded to my annual visit home. There my radio engineer brother took the radio and gave it his close attention, puzzled over it as had I, and concluded a defective part somewhere. This he soon found in the tuning capacitor which had had a connection slip off its set point. This easily corrected, the radio seemed ready for testing. Unfortunately he did not have an antenna handy (he works in uhf+ research stuff) so all I could do was hook the set to a signal generator and test its performance, summarized below.

at 3 turns and 8 turns from the ground (center) of the coil. I ended with 9 turns on the final set with testing giving me a 7.6 mH coil. The final schematic presented below.

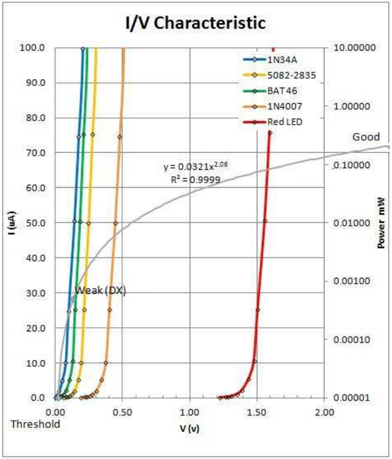
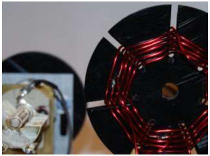
The above is an interesting plot taken from the text discussion in "Crystal Set Analysis" by Berthold Bosch. It presents received signal strength across the tuned circuit for various scenarios from threshold audibility to local blowtorch. This plot should be considered a single example specific to his location and antenna/ground system. In the text he describes his antenna an an inverted L 43m long (140') and 10m high (32'), an excellent antenna most of us do not have the real estate to erect, but offsetting this is a poor ground with Rg = 210ohms. Given the offsetting conditions I would imagine this is a good generic example of what received signal voltage and power levels presented across the LC circuit to the diode are likely to be. Bosch cited 40nV as the threshold of audible detectability (impedance matched conditions with 16kohm RF impedance / 4kohm DC phones) and for this plot I pushed it back to 20nV as it gave a superior regression fit.



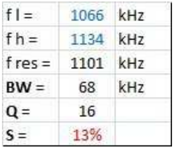
This plot at left takes some actual diode I/V measurements rather than the models presented below and plots them along with the above RF voltage across the LC circuit versus RF power in mW. Here one sees that pushing for very very low Vf (via high Is / low n combinations) pushes the limit of detectable signal power from the antenna. At such minute power levels I imagine the reverse leakage current becomes significant and probably offsets the low operating point gains sought.

Global DX'ter
http://www.lessmiths.com/~kjsmith/crystal/sw2.shtml



Finally, a shortwave set comes off the design bureau and out into the world. This is a type of set I have been planning and pondering on for some time. With many crystal radio design possibilites this will certainly not be the only SW set I plan, but it is my first effort, my chance to "do it" on shortwave. For a first effort I settled on a fairly simple design, a single-tuned rig with some degree of control, but not overly much. I took as my base a design by Rainer Steinfuehr on his Crystal Reciever World site. This design features a high Q spider coil with two taps, and adjustable capacitance on both the antenna and tuning circuits. It made a rather lovely small set indeed.

The specifics of the design were entirely my own and were based on the frequency range I wished to target and the specifications of the materials I had available for the project. In partictular, I had available small good-quality 10 - 115 pF variable caps for which my clever elder brother had lathed lovely 1/4 inch shaft extenders for use with standard tuning knobs. My target spectrum was about 5 to 18 MHZ as that is where the dominant international BC action takes place. With luck that would also allow receiving WWV at 10 and 15MHz as well. Digging into the design spreadsheets, it seemed an inductor with 7 to 9 mH would best deliver the goods. I made a spider form from a circlar cut of 1/8 inch Delrin plastic and wound 11 turns of 18awg magnet wire, carefully soldering taps

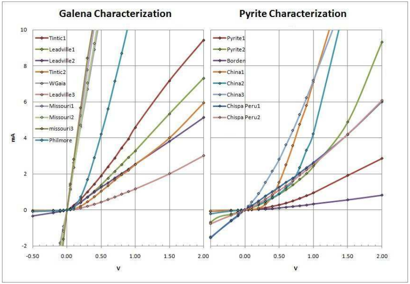


f l =	1066	kHz
f h =	1134	kHz
f res =	1101	kHz
BW =	68	kHz
Q =	16	
S =	13%	

Performance summary of my Bremer-Tully Set is so so with a set Q (loaded) of 16, -3db bandwidth of 68 kHz and a sensitivity calculation only 13%, not so great. I rather expected as much as this is a single-tuned set of very simple circuit design. Compensating slightly is the fact that it tunes with a single dial which is certainly more user-friendly. It does require a wave trap to cut out powerhouse KGOW blazing away and flooding the entire BC band on this set if left untrapped. Most of my radios have higher sensitivity so this set definitely benefits from my audio amplifier.

Bank winding in six banks: 4 wires / side, 10 windings per bank, times 6 = 60 turns. Coil form 3 inches in diameter, space wound 0.8 inches wide calculates to 376 uH, pretty close to my measured 377 uH. Measurements: Primary B-P = 20 uH. Secondary F-G = 377 uH, G-T = 210 uH, T-F = 65 uH. I know, 65 + 210 not equal 377, I measured it several times to be sure!

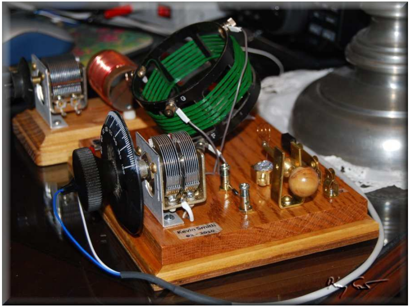
Crystal Galena and Pyrite Diodes



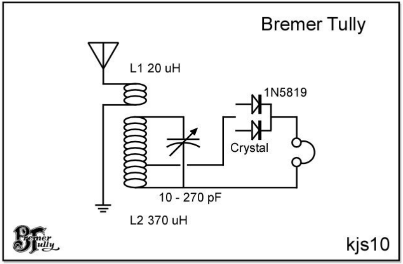
The above curves demonstrate the wide variation in properties and qualities that can be found in natural crystals of galena or pyrite, the two most common and best quality natural stones. In each crystal test I first poked around the crystal for some time to 1) determine a typical sensitivity for the crystal in question and 2) to locate the best hot spot with which to test. This turns out to be a non-trivial exercise on the diode test setup. In a crystal radio one need only listen for the loudest spot. With the test setup one needs test both the forward and reverse current in order to determine if the whisker is on a hot spot or not. Very tedious work! (In retrospect, if I were starting over making a test jig, I would definately add a DPDT switch to readily change between forward and reverse current measurements. I'd probably toss in a rheostat for fine adjustments as well).

For many crystals there are limited number of possible hot spots, but these may be hot indeed. For most of my "Steel Galena" samples (Tintic Utah, or Leadville Colorado) there are numerous hot spots under virtually every place I touch the probe, but in general the sensitivity is good to so so. These crystals are very kind to work with in terms of finding spots and avoiding frustration. Mirror galena on the other hand may have quality hot spots, but any hot spots at all are rare and frustratingly difficult to locate. Here my Philmore detector crystal shines with an almost ideal "Galena" response. To chase down this rabbit I purchased some lovely mirror galena from Sweetwater Missouri. I broke off a few appropriate-size chunks to pot in woods metal and test. At first I was very excited with the high currents I was seeing at moderate voltages. Figured I had struck gold. When these crystals failed miserably to rectify anything in my radios, I re-measured things in both forward and reverse directions. These crystals obey Ohm's law and act like typical resistors, not suitable for radio work at all.

For my pyrite crystals the work has been especially tedious and frustrating. With one of the crystals one "hot spot" alternated, entirely on its own, between hot and bad while I was making the measurements. I would start over and over, sometimes getting interesting readings then suddenly it would drop to low values and I'd start over, back and forth. I present this data as best as I have measured, and I don't intend to go back! You see at least one of the crystals, my "China 1", (from a lead/silver mine in Hunan) gave a sweet classic-looking curve. More to the point, "ideal" curves for natural minerals, are difficult to come by. Most crystals you use will be less than ideal. The good news is that, while listening to your set, poking about for a good spot is far easier than what I have



Circuit schematic for the set.

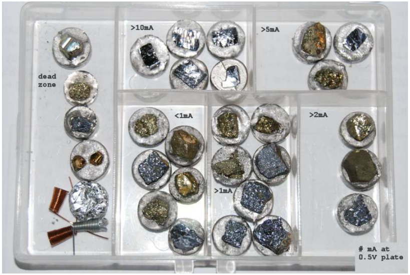


tune down to 500 kHz. The closest variable cap I have found is a cute little 2-gang 10-270pF unit. This is as low as I have found at the low end for a standard-configuration variable cap. The goal then is to try and keep the circuit capacitance as low as I can, which I translate into keeping the circuit as simple as possible.

My circuit is further constrained by the coil itself. It is essentially an "oatmeal box" type setup with an aperiodic small inductance primary and large inductance secondary. Tuning then must be single on the detector side only. My only option is whether I connect the crystal/diode to the tap post or to the top of the coil. I went with the tap, so shoot me! One complication I maintained, as I do on all my sets, is to keep a switch between using a crystal and cat's whisker or using a diode. In this case I chose a Schottky 1N5819, the most sensitive diode I have yet tested, (diode test). I have yet to test just how high on the BC band I can tune, but KGOW at 1560 kHz sure gives me trouble.

---

gone through to produce these curves. Your ear will take care of you!



In the photo I indicate groupings based on an easy measure of performance. I note the current in milliamps for each set where the plate voltage is set at 0.5V. The greater the current the better are your chances to get a sensitive crystal, assuming Ohm's Law is not followed! Crystals in the "dead zone" on the left will have their woods metal re-melted for new detector crystals and the bad ones tossed, its tough love for crystals. I find that easily half the potted crystals I make are tossed this way, and only a few can be considered superlative.

Vacuum Diodes

When I decided early on to construct a radio based on the vacuum diode (see my Fleming Radio section), I had to find a suitable tube for the project. That began with an extensive search through the datasheets checking vacuum diode properties and reviewing the characteristic curves for a large number of diode tubes. In the above figure I plot the characteristics as best I can on a commpn plot for comparison. I was hoping to find a good candidate with sensitive characteristics and low energy consumption. As you will find, such a beast did not exist. Following this research began a period ot purchase and testing.

I have tested seven different tube types including 6.3V rectifier diodes that take a lot of power to run and are not really suitable for battery use, a 9v dual diode tube (20D1), a pentode/diode tube (1S5) that is designed to run on a battery at 1.5V and 50mA, and a couple miscellaneous but cute tubes. In testing the 1S5, I found the filament never glowed incandescant at 1.5V and, on measuring, was barely sensitive to anything. I cannot imagine this tube would make much of a diode for crystal radio use. I tested different manufacture 1S5 tubes from two different suppliers. No dice. Finally, I tried to push the tube to operate at higher-than-specified voltages. At 4.3V the I-V curve was still very flat, but shifted slightly higher, crossing the Amp axis at about 0.4 mA, (see graph). At 5.5V one of my tubes gave up the ghost and I didnt do more. I pretty much rule the 1S5 out for my crystal radio work. Looks like i'll be needing the power supply when I get around to building/operating that Fleming Radio.

A question remains as to what in fact is different about these tubes to give such different characteristics. While the I/V

A Bremer- Tully Transformer

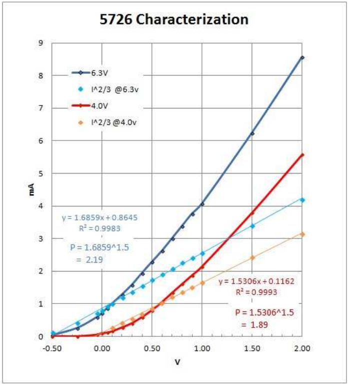
AC-1
AIR CORE TRANSFORMER
SERIES BANK WINDINGS
TYPE

I recently won on eBay and lovely NOS Bremer Tully air core transformer its inspection tag still faithfully wired to the base, (and so it will remain on the final radio). It is absolutly gorgeous and I was the only bidder when it sold, for such a great price! Honestly, I was not totally sure what I was getting when I bid other than it looked like a coil and, from the ebay photo, maybe would work for shortwaves. Calling it a transformer was confusing although I understand all coupled coils are transformers. Perhaps that is why I was the only bidder, well, so much the better! When it arrived I got a good look, very interesting winding technique. The tuning coil is wound with somthing like #30 dcc or dsc wire. The winding is in 6 bank-wound groups of about 10 windings each. Inside is a small primary antenna coil. I promptly got out my handy-dandy inductance meter and measured 377 uH on the tuning and 20 uH on the primary. In addition, there is a tap on the tuning coil one "stack" in. 377 uH is a bit on the high side for BC work and I'm not sure I'll ever get the top end of the band but still, the transformer works beautifully.

My calculations for a setup using a 377uH coil suggest that a minimum total capacitance of 23 pF will allow tuning up to 1700kHz. This is a tall order, most variable capacitors I have found have a minimum value in the 20 - 25pF range. Add another 15 - 25pF of stray circuit capacitance and I am way over the line. The good news is that only 270pF is needed to

characteristic of most vacuum diodes pretty much follow the Langmuir-Child Law, the steepness of the I/V characteristic is largely due to the geometry of the tube elements and the volume of electron space-charge between them. JB Calvert's Theory of Vacuum Tubes informs one that this is the property called Perveance in a vacuum diode. Measuring this requires plotting I raised to the 2/3 power against V and taking the slope of the best-fit line through the data. This slope raised to the 3/2 power is the perveance. The following chart illustrates graphically the relation bewtween the tube characteristic and perveance. For the 5726 tube I plot the characteristic in dark blue for the tube heated with the design 6.3 volts. In light blue I have plotted the measurements and raised them to the 2/3 power. One sees immediately that the new curve is linear. The slope of the curve raised to the 3/2 power yields the perveance factor for the tube.

(Note in addition that when running the tube at a more sensitive point with 4 volts only on the heater the perveance is slightly less than spec.).



With my measurements calculating the perveance is practical and quickly done, results as follows:

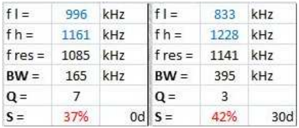
Tube	Perveance	R2
6C19P	2.54	0.997
5726	2.19	0.998
6DN3	5.40	0.997
20D1	2.02	0.985
5C12P	0.32	0.999
1S5	0.063	0.999
2D1S	0.155	0.975
6G2	0.050	0.999

however, is NOT the inventor of the oscillating and regenerative feedback circuit, which forms the basis of all radio amplification and truly opened radio to a mass mode of communication. This honor goes to E.H. Armstrong, the man who dug into the tube and worked out correctly for the first time its basic theory and operation. The two men fought a bitter 19-year litigation battle over this honor that in the end was awarded to De Forest by the Supreme Court in what amounts to a technicality.

From what I have read of De Forest’s writings, patents, and exchanges with Armstrong in the Proceedings of the Society of Radio Engineers, it is pretty clear that De Forest never really understood how his tubes worked. So, he was never in a position to develop the tubes to their full potential. Armstrong for his part seems to have treated De Forest with academic contempt. Armstrong went on to invent the super-heterodyne (1918) and super-regenerative (1922) amplifier circuits and created almost single-handedly FM radio (1933) as we know it today. His life ended in tragedy, representing the closing chapter in the age of great individual inventors, finally crushed by the greed of corporate America. Virtually all advances following his were the product of team efforts in company or government research laboratories.

If therefore you have misgivings as to my honoring De Forest with a radio, please understand I do so not for his Supreme Court victory but to honor the inventor of the triode tube, a debt which even Armstrong would always acknowledge. Should you still feel uncertain, then just enjoy the sweet irony in honoring the father of the triode tube with a crystal radio.

De Forest circuit diagram (aka Sleeper #18).



f l =	996	kHz	f l =	833	kHz
f h =	1161	kHz	f h =	1228	kHz
f res =	1085	kHz	f res =	1141	kHz
BW =	165	kHz	BW =	395	kHz
Q =	7		Q =	3	
S =	37%	0d	S =	42%	30d

Performance summary of my DeForest is really just abysmal, it has a low set QL of 7 reflecting a huge bandwidth of 165 KHz but my sensitivity calculation is 37% for the condition of tight coupling. This set clearly trades Q and bandwidth for sensitivity. The set is technically double tuned with variable capacitance in the detector circuit and variable inductance via taps on the antenna circuit. The inductors are loosely coupled via rotating the inner inductor with respect to the outer. What I discover in fact is that rotating the inductor changes the tuning and so it "feels" more like a variometer rather than a variocoupler. Rotating the rotor 30 degrees to loosen the coupling does not narrow the bandwidth, in fact it increases to 395 KHz. I have much to test still on this set, it is a disappointment as I expected a much better QL. Measurements were made with the detector circuit farily optimized for a test frequency of about 1100 kHz, but I wonder if I can better optimize the tap settings for the antenna circuit. More to come.

What’s in a name?

The name De Forest in the history of radio is one few engineers can hear without a fairly strong opinion. Dr. Lee De Forest is the acknowledged inventor of the triode radio tube. De Forest

The perveance numbers above range from 0.02 to over 2 mA/V^3/2 (with >2 being good for small-signal detection) and clearly shows my choice of the 6C19P to be an excellent one. I am surprised to see a huge 5.4 for the 6DN3 diode, a color television damping diode. It takes a Novar 9-pin socket and is a large tube so doing more with this tube may have to wait a bit.

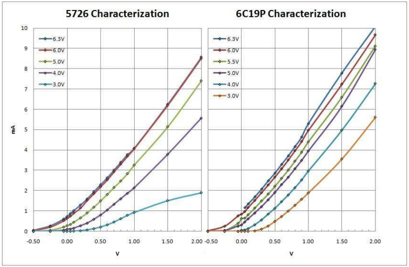
Calvert's 2001 published data

Tube	Perveance
6AL5	2.42
6H6	0.50
7Y4	0.58
2X2A	0.017
6V3-A	2.3
6AX4GT	1.42
6AV6	0.085
1A3	0.075

The high-perveance diode tube types I tested show an interesting property in that their characteristic curves do not pass through the origin of the graph. These curves are wholly acceptable as crystal radio detectors although they will require power to operate. What I have noticed with such tubes is that when I turn them off after using them with a radio, on cooling they go through a period of much increased sensitivity (very loud) before fading to nothing. It is as though running them at the full 6.3V lowers their full potential as crystal radio rectifiers. The reason is in the high perveance of the tubes, the anode is already proximate to the space charge before any plate voltage is applied. Effectively, while the plate (anode) "Zero" voltage is measured with respect to ground, the plate itself is still positive with respect to the cathodic space charge.

Small currents will continue to flow even with a negative bias to the plate, (Contact potential).

In order to explore this idea, I ran a series of tests with the tubes running at lower operating voltages (effectively diminishing the space charge thus lowering the perveance) as shown:



Here you see the impact of lower operating voltages. With the tube operating between 3 and 4 volts the characteristic curves begin to pass through the origin as in regular solid-state diodes and crystals. It is precisely in this voltage range that I found the radio sensitivity, as measured by loudness to my ear, to be most pronounced. It appears that the diode characteristic needs to pass through the origin of the I-V graph for highest sensitivity. This takes me to the 20D1 tube which operates at 9v but only 200mA. This will still take a power supply to use, but the good thing is that the characteristic curve passes

---

View from above highlighting the tap wiring, SO much work!

through the origin. Running at its design parameters the tube looks a lot like the 6C19P at 4v.

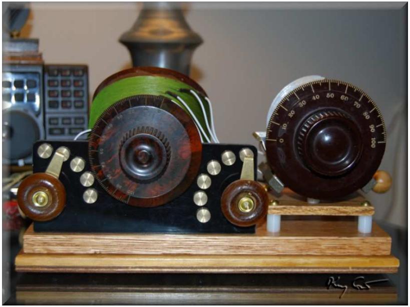
on each switch. The wood knobs have a nice easy action, the switch passing readily between contact buttons.

The radio works quite well, in its tightly-coupled setting it is quite sensitive with a strong signal. Its selectivity on the other hand leaves much to be desired. This can be expected from the circuit layout with only the secondary circuit capacitively tuned and the detector tied at the top. I was hoping that by varying the coupling I could achieve some increase in selectivity, but it de-tunes the station with an additional unacceptable loss of sensitivity. Take this outside the urban environment with such crowded airwaves and the set ought to perform admirably. Signals come in strong with the steel galena nearly as well as with the diode. I like this set.



Portrait of set, ummmm..

As most of the components for this set were ready made, the construction planning felt a bit much like assembling a kit. I had originally intended to use modern tap-selector switches as well. In order to make the construction challenging, and more importantly, to maintain the vintage look and feel of the set, I quickly abandoned the modern switches and chose to fabricate instead classical wiper switches in the early style. Of course, I also include my own style cat’s whisker and SPDT knife switching to a more modern diode. The diode is my only nod to post war technology. In the crystal cup I have some lovely Utah steel galena potted in wood’s metal, finely crystalline, hot as hell all over its surface.

As one can clearly see, my obvious preference is for the breadboard style of early radio. Much of the fascination and beauty of these sets lies in the component hardware. To enclose them behind panels or put them in boxes seems such a waste. The base is a box with about ¼ inch of space inside to hide the bolts and wires. I did need a small panel to place the wiper switches on. This is made of 1/8 inch black Delrin plastic resin, a very hard and nice to work with material. In fact though, it is a bit too shiny, too “plasticy” for my taste. Well, that is what I had.

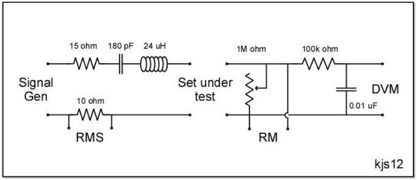
Fabricating the wiper switches, buttons, and leads to the inductor was an odyssey in its own right, amply satisfying my desire for more challenge. Attaching the leads to the primary, soldering without damaging the windings, and the added touch of shrink-wrap “mittens” was a labor of love. I do hope it is justified by the final presentation. The rest of the construction and wiring was a piece of cake by comparison. The wiper switch knobs are wood with a felt buffer against the panel. Behind the panel compression springs keep a steady pressure

RADIO TEST

Kevin Smith
http://www.lessmiths.com/~kjsmith/crystal/rtest.shtml

OK, now that you have built a radio, or several, how do they perform? Without a bit of objective testing you will never really know. I have often read descriptions of radio performance such as "tunes very sharply" or "separates two closely spaced stations" and/or etc. These are qualitative descriptions that do not really give you much information. To know your radio, it takes some measuring. I am making the assumption here that, as a homebrew radio builder, you will find tinkering and measuring your sets just as interesting as their design and construction.

For testing, I have pretty much lifted the excellent procedure outlined by Charles Lauter with a few modifications to suit my own philosophy. I will give my own protocol but first let’s look at the needed equipment and test setup. Testing a crystal set requires two pieces of homemade equipment, a dummy antenna in front of the set which allows measurement points, and a measurement load at the back end. Other pieces of equipment include a signal generator, an rms voltmeter, a resistance meter, and a good digital voltmeter. Circuit schematics for the homebrew components are shown below.



For the tests I originally found an old analog signal generator on ebay which I sadly found to be wholly inadequate. The unit was by no means cheap but the dial was difficult to read with any precision and the "play" in the dial made readings hopelessly inaccurate. Finally, it gave no indication of the attenuation or voltage output levels, rms or pp, of the signal. I have since found a nice, reasonably-priced new digital unit, (max's out at 2Mhz so strictly for AM band work) that gives good readings, gives me the output voltage level in pp, and can even produce different wave forms. I recommend if you are seeking to equip your lab, go this way from the start!

To calculate the signal input power you will need a good rms voltmeter. This is a non-trivial item and, after my experience with the vintage signal generator I was leery of getting a used meter. In any case, an expensive dedicated single-use piece of equipment seemed extravagant. For this measurement I have found entirely acceptable results using an oscilloscope which, of course, is useful for so much more and belongs in your lab regardless!

It is on the back end of the measurement where I diverge from Lauter's protocol significantly. He recommends placing in all

De Forest, Vintage beauty

http://www.lessmiths.com/~kjsmith/crystal/deforest.shtml

My latest effort, I call this my “DeForest” after the principal component of the radio. Over the last few months of visiting ebay and finding essential radio parts and browsing, I have stumbled across an occasional vintage piece that I just loved and needed to bid aggressively on. My intent is not to just stash these in a drawer somewhere for the pleasure of owning, but to use them in projects. This project is built around a lovely De Forest Radio Telephone and Telegraph Company Vario-Coupler. The vario-coupler, wound in beautiful apple-green silk covered wire 24 gauge or so, has a tapped primary stator measured at 560 uH and an untapped internal rotor of 285 uH. Other vintage components in this set include a Windham square-law tuning variable capacitor, 20 to 550 pF, and an Atwater-Kent 3 ¼ inch tuning knob. The second 3 inch knob on the vario-coupler is a vintage Radion Dial made by the American Hard Rubber Co.

I built the radio according to Sleeper hook-up #18. It is a fairly straightforward hookup but with sophisticated features including a double-tuned design, a tapped primary tuned via single and multiple taps, and variable coupling. The secondary coil is tuned with a vintage variable capacitor. As the secondary coil is the rotor inside the primary, there is no provision for tapping and the detector circuit is connected to the top of the coil. This set could use some selectivity enhancement circuitry I suppose, but oh well...

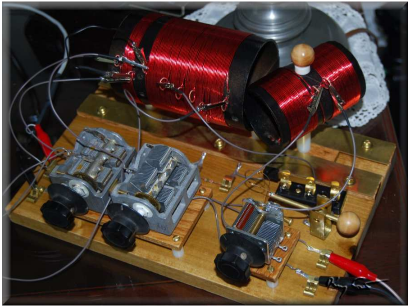
radios to be tested a 1N34A diode and then use a standard 2k ohm load resistance to make the output measurements. This may give a standard and comparable result, but it does not insure a good impedance match and does not reflect the intended usage and setup of many crystal sets, especially sets intended for high-performance. Here I am interested to learn just what is the optimal load resistance for my set under the test conditions. Note the caveat "under the test conditions". This may not reflect actual usage unless you take precautions. You will want to set the generator to an input voltage similar to what you expect the radio to receive in actual operation. You will probably want to signal level work the diode in its peak-detection region but not so high as to saturate the diode, (In making a loaded Q measurement you want to make sure that the diode impedance stays constant; otherwise, the change in diode impedance (as the tank attenuates the signal before the diode) will change the load on the tank and the bandwidth measurement won't really reflect the Q of the tank). Finally, for the output voltage you need a good voltmeter with very high input impedance that will not load down the set under test. This really means a good DVM. I use a used Keithley 192 bench meter with a 2M ohm input impedance, and as a backup a used Keithley 180 bench electrometer. Overkill perhaps, but for just in case...

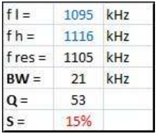
Getting back to the load resistance then, my protocol is to find the optimum resistance to deliver the maximum power (not voltage!) to the load. This is a bit of a tedious process but will amply rewarded. Having tuned and peaked the set to the measurement frequency, I then take a series of resistance/voltage readings to find the maximum power output. In my circuit this is accomplished with the variable 1M pot. The resistance meter and voltmeter cannot be connected to the load at the same time making this a tiresome road to follow.

Once I find the optimum load resistance, I set the pot to that and proceed to the main testing for sensitivity and bandwidth/Q measurements.

Test Protocol as follows:

1) Connect the set to be tested between the dummy antenna and measurement load as per the above diagram.
2) Connect the signal generator to the dummy antenna and set the frequency and voltage output. I typically test in the center of the BCB at 1100khz and use a 200mVpp output sine wave.
3) Set the load resistance to somewhere around 50k ohms. The exact value is not critical as it will be adjusted later.
4) Connect the DVM and tune the set to peak the output voltage. Care here is amply rewarded, especially with double-tuned sets.
5) Once peaked it is necessary to adjust the generator frequency to re-peak the output voltage as hand-capacitance or other factors may have prevented perfect tuning. You now have your set properly tuned for maximum output. Presumably this also means the best possible impedance match between the set and dummy antenna. This is the resonant frequency (f res).
6) Record the frequency and output voltage.
7) Now find the optimum load resistance. This is done by making a series of paired measurements of load resistance and output voltage. Power in uW = mVout * Rl khoms.
8) Set the load resistor pot to the value where power output is highest, this is the optimum load for the test. Record this.
9) With the signal generator re-peak the output voltage and re-record the resonant frequency (f res) and output voltage (Vout mV).
10) Multiply mVout by 0.707 to find the -3dB level.



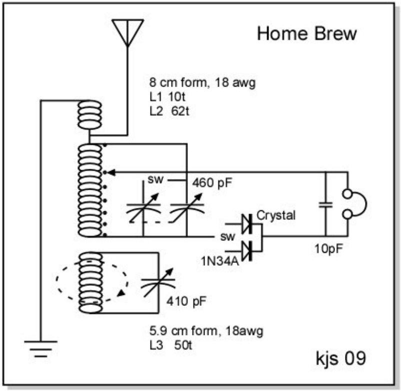


f l =	1095	kHz
f h =	1116	kHz
f res =	1105	kHz
BW =	21	kHz
Q =	53	
S =	15%	

My homebrew in its Galenatron configuration shows fair Q at 53 and poor-fair sensitivity of 15%. There is a 1cm separation between the antenna coil and detector coil which may help. In many radios of this design I see the coils separated by 2-3mm only. As I wound the coils on a single form, there is no experimenting here, just wondering. The variocoupler here is only a trap and was not used in this measurement. With the return to a single-tuned set you need expect performance downgrade, but greater ease of use for general listening. I feel this configuration is a good compromise for easy listening without the hassel fo manipulating two (or more) tuning dials. It is clearly superior to the Dunwoody and De Forest single-tuned sets.

general listener radio and far far from the performance achievable in high-quality DX designs. But it is teaching me as intended.

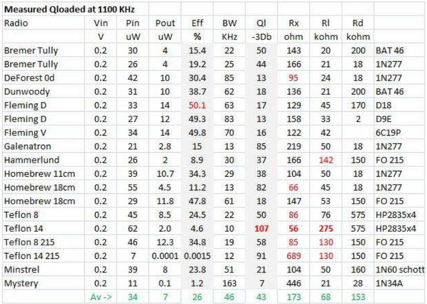
Inspired by Dan Petersen's Galenatron, I wished to play with a vario-coupler design. This hookup uses a single form with an antenna coupling coil of 10 turns and a tapped secondary coil with 62 turns. The first 2-gang vcap is unused. The single-gang variable cap tunes the rotor. So far the best position seems to be keeping the rotor in-line with the main coil. More learning to come.



11) Adjust the frequency above and below f res until the output level falls to the level calculated in step10 above. These frequencies are f high and f low. Record these.
12) The -3dB bandwidth = f high - f low. Loaded Q (QL) = f res / BW
13) Take the generator output peak-peak voltage recorded in step 2 above and convert it to rms voltage as follows: mVrms = mVpp / 2.829. This is Lauter’s RF voltage E1 mV.
14) Measure the RF voltage across the 10 ohm resistor on the dummy antenna. This is Lauter’s RF voltage E2 mV.
15) Input current to the dummy antenna = Lin = E2/10 (mA)
16) Input power to the dummy antenna = Pin = E1 * Lin (uW)
17) Power loss in the dummy antenna = Pda = Lin^2 * 25 (the dummy antenna resistance)
18) Power delivered to set = Px = Pin - Pda uW
19) Set input resistance = Rx ohms = Ex / Lin where Ex = E1 - (Lin * 25)
20) Set output power (uW) = Pout = Vout^2 / Rl in ohms
21) Set % efficiency (sensitivity) = 100 * Pout / Pin

Having built a fair number of sets, and with varying quality, all the above protocol was developed to test my sets. What follows now is a discussion of how my sets stack up against each other and some notes on what one may expect in a crystal radio performance-wise. I give a summary table below of the essential data gathered on each of my sets.

Table 1



Measured Qloaded at 1100 KHz

Radio	Vin	Pin	Pout	Eff	BW	Ql	Rx	Rl	Rd	
	V	uW	uW	%	KHz	-3Db	ohm	kohm	kohm

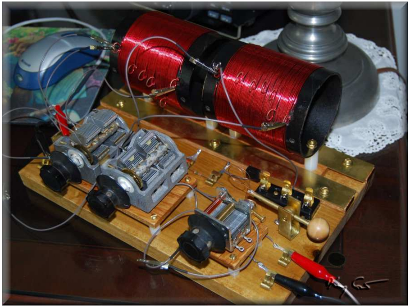
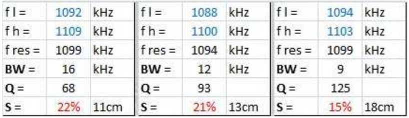
	Av ->	34	7	26	46	43	173	68	153	

The above table of measurements were made at a nominal frequency of 1100khz and input voltage of 0.2Vpp as indicated on a digital signal generator following the protocol outlined. I give the radio name under test should you wish to refer to my pages for more on each set. The columns as follows:

Vin = 0.2V pp (0.71mV rms)
Pin = input power in uW into the set (after the dummy antenna)
Pout= output power across the load resistor in uW
% Eff = 100 * Pin/Pout
BW = bandwidth in khz at -3db
Ql = calculated loaded Q of the set
Rx = the set input resistance presented to the antenna
Rl = measured optimum load resistance for maximum power transfer
Rd = Diode junction resistance Rd used in the set





f l =	1092	kHz	f l =	1088	kHz	f l =	1094	kHz
f h =	1109	kHz	f h =	1100	kHz	f h =	1103	kHz
f res =	1099	kHz	f res =	1094	kHz	f res =	1099	kHz
BW =	16	kHz	**BW =**	12	kHz	**BW =**	9	kHz
Q =	68		**Q =**	93		**Q =**	125	
S =	22%	11cm	**S =**	21%	13cm	**S =**	15%	18cm

Here I show the performance summary for my set with three coil separations, 11cm, 13cm and 18cm. With these charts you see the value and trade-offs in loose coupling between the antenna and detector circuits. With the coils at 11cm separation they are slightly over-coupled but still with relatively good Q, 68, and fair sensitivity at 22%. Separating the coils to 13cm and then to 18cm loosens the coupling allowing narrower bandwidths and higher Q (getting to 125, woohoo!), but at the sacrifice of much sensivitity, down to 15%, still reasonable. This is an excellent performance, I must be doing something right somewhere. Of course this is still a

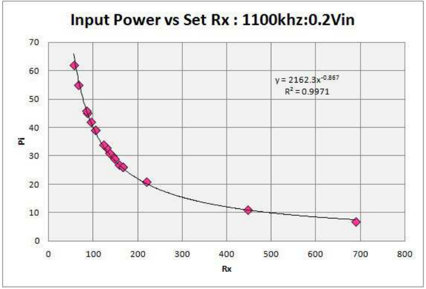
From the data above some interesting observations can be made.

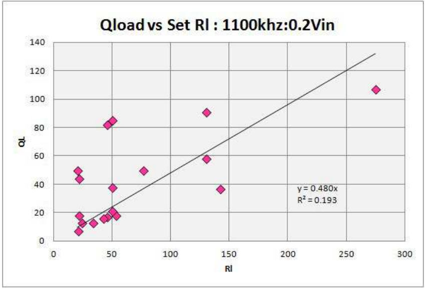
Figure 1.



In figure 1 above I show the relation of the input power versus the set resistance. The quality of the fit reflects that fact that this is largely a calculated value, but it does illustrate the importance of having a low input impedance to match that of the antenna. This is not often considered in discussions on impedance matching but is critically important. The antenna has an impedance in the 25 - 50 ohm range, not easy to get this in a set without quality parts and construction. My sets typically have an input impedance in the low 100's ohms and only two of my sets really get down to the 50-60 ohm range giving a good match to the antenna. Both of these are double-tuned sets with a tuggle front end.

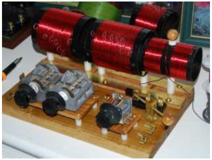
If you are serious about getting DX and doing a lot of heavy lifting, you will need a good antenna tuner as part of your set design.

Figure 2.



At the back end of the set things get a bit messier and are not east to show with a simple two-component plot. Here I have chosen to highlight the importance of the proper load resistance on the set loaded Q. In my set testing I have tried to pay close attention to the importance of the load on the tank and diode. Early on I considered construction of an output transformer unit that would work with different radio’s as well as with different phones. Such a design can be found on Ben Tongue’s excellent and highly technical web site. The plans were well beyond what I was able/willing to take on so I turned my attention to discovering just what load resistance exactly do my sets require for maximum power transfer. After all, if I found only a small range typical values, I might design

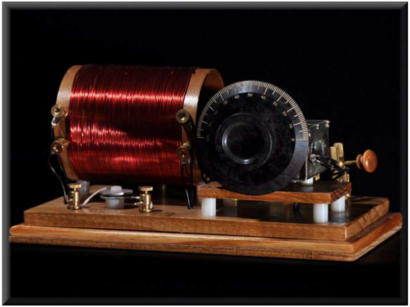
My second homemade, A double-tuned open test bed
http://www.lessmiths.com/~kjsmith/crystal/homebrew.shtml



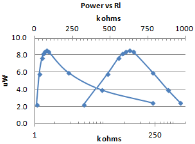
Having learned my lesson with the Mystery set, I have set myself to make a double-tuned rig with open wireing for testing multiple configurations. The concept is to seek the maximum amount of flexibility in hookup and coil design. This will mean interchangeable coils with or without taps, and wireing with allegator clips. I have chosen to hard place in the set three capacitors, 2 double gang 20 - 460 pF and one 20 - 410 single unit. The detector, as always, will switch between a diode and my own crystal stand. The modular design will allow testing coils mainly although vcaps will also easily be tested with jumpers. The number of leads and allegator clips, not all used with any one configuration will give this a bit messy look, but this is not a beauty contest but for learning. As always I include the option of using either a germanium diode or actual crystal.

The photos and circuits below show two hookups currently completed.

Double tuned circuit with tapped coils and an optional QRM trap (unused in photo). This configuration alone will keep me busy quite a while! I am learning what "sharp" tuning is. The antenna coil is tunes series-parallel but the first, (left) 2-gang vcap while I only use one gang of the second vcap. For lower inductance coils I can use the second gang in parallel.



a generic transformer that would work well with many or all minus the complicated switching.



In my testing protocol therefore, I included the important step of determining the optimum load resistance for the set under test conditions. I certainly part company with the school of thought that says to test all sets exactly the same way, including same diode (1N34A typically) and same test load. Sets are designed to work best when impedance matched and at the back end that generally means a load matched to the tank/diode combination that delivers the maxumum power. At right above I show a small plot where I varied the load resistance over a wide range and calculated the output power of the set. (I give the plot with both a linear and a more appropriate log scale). This should demonstrate the importance of optimizing the load resistance.

Optimum load resistance depends on both the tank Q and that portion of the diode detecting the signal. That in turn depends on the signal level. Very weak signals will be rectified in the square-law region of the diode characteristic and require relatively high (and variable) load resistances. Normal to strong signals will be rectified primarily along the peak-detection portion of the diode characteristic and require lower load resistance with less variation. Not shown in the above spreadsheet, I also ran measurements with a 2.0Vpp input. With this stronger signal, rectification was taking place farther out on the diode characteristic. As expected, the measured optimal load resistances for this case was similar to or lower than that for the 0.2Vpp input case.

With all that said, the plot in figure 2 is messy but the impression is that of increasing Q with increasing Rl. I view the plot as having a number of small groupings of measurements with similar conditions, each showing higher Q's associated with higher load resistance.

Figure 3.

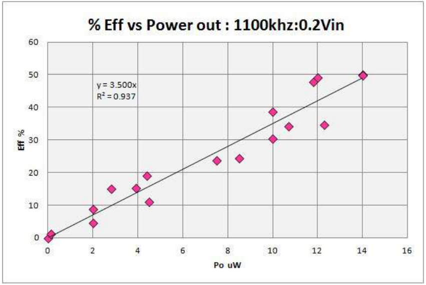


Figure 3 is most obvious with the clear benefit of good set efficiency on output power. An efficient set will better approach the maximum power transfer desired. High Q plays a part here. Still, there is always the tradeoff between selectivity (high Q) and sensitivity. An efficient set delivers more power to the load, but to go after Q you will ultimately be sacrificing sensitivity.

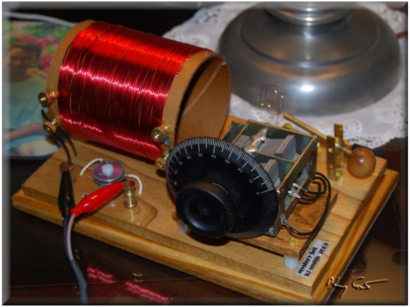
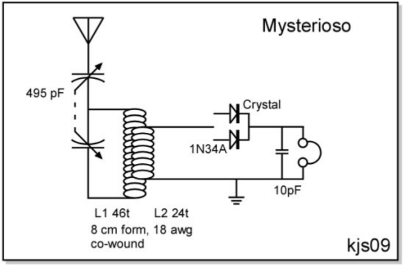
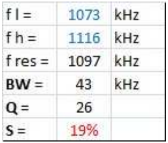


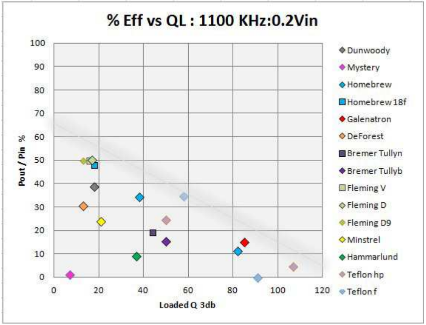




f l =	1073	kHz
f h =	1116	kHz
f res =	1097	kHz
BW =	43	kHz
Q =	26	
S =	19%	

Performance summary for the radio. My Mystery set, despite initial mis-calculations on the coil winding specs, turns out to be a fair performer. the bandwidth around a nominal 1100Khz is 43Khz giving a set Q of 26. This result is superior to both my DeForest and my kit Dunwoody, not bad for a first try! Sensitivity comes in at 19%, second after the DeForest. So, I consider this a successful entry into the world of scratch-built crystal radios.

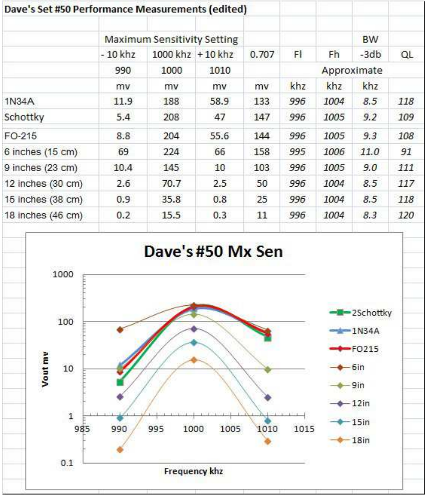
Figure 4.



Here is the bottom line, Q verses Sensitivity, efficiency in this case. On this plot it is readily evident that I have built my fair share of loser radios, but also a good number of sets which push boundary of what can be achieved in terms of compromise between Q and sensitivity. Looking at the plot it is fairly easy to imagine a sloping line or zone running from 0 Q at 60% efficiency down to 120-130 Q at 0% efficiency. Beyond this one will probably never go with tank and antenna tuner alone. It will be time to start adding traps to your bag of tricks. Recall that the above is for the 1100khs frequency and that Q is a function of frequency.

In order to explore this final conclusion, I have taken a look at Dave Schmarder's excellent bandwidth analysis of his #50 contest set. This set is a superb work of craftsmanship and skill, experience and usage of the best ($$$) materials available. I take this to be just about the most of what can wrung out of the sky with a crystal radio. Dave’s protocol is rather different from my own and he did not make a specific -3dB bandwidth measurement so what I do from here on takes many liberties with his work, my sincere apologies in advance!

Figure 5.



Dave's Set #50 Performance Measurements (edited)

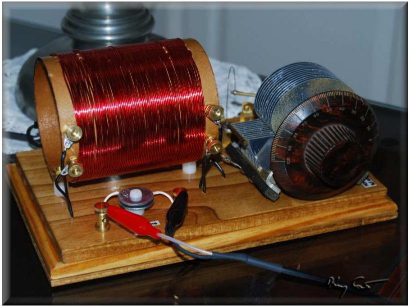
	Maximum Sensitivity Setting						BW	
	- 10 khz	1000 khz	+ 10 khz	0.707	Fl	Fh	-3db	QL
	990	1000	1010		Approximate			
	mv	mv	mv	mv	khz	khz	khz	
1N34A	11.9	188	58.9	133	*996*	*1004*	*8.5*	*118*
Schottky	5.4	208	47	147	*996*	*1005*	*9.2*	*109*
FO-215	8.8	204	55.6	144	*996*	*1005*	*9.3*	*108*
6 inches (15 cm)	69	224	66	158	*995*	*1006*	*11.0*	*91*
9 inches (23 cm)	10.4	145	10	103	*996*	*1005*	*9.0*	*111*
12 inches (30 cm)	2.6	70.7	2.5	50	*996*	*1004*	*8.5*	*117*
15 inches (38 cm)	0.9	35.8	0.8	25	*996*	*1004*	*8.5*	*118*
18 inches (46 cm)	0.2	15.5	0.3	11	*996*	*1004*	*8.3*	*120*

More study, more puzzling over the problem, more calculations, more frustration, more more study.. Did I say that? Short of complete disassembly, which I was loath to do, I was unsure where to go with it. Reading all I could, I came across a set with a modification with a second cap tuning the antenna, this I could test! My antenna, by the way, is a 100ft 14g stranded insulated copper wire with an additional 30ft or so of lead-in. Tuning the antenna seemed promising and when placing a cap the set suddenly found its voice! With a working radio, I had the dilemma of what to do with the case. No second cap would fit. The large vintage capacitor could easily be replaced by two small modern caps though and testing showed that in reality they tuned very effectively with a dual-gang capacitor which is what I settled for in the end. The set still dosnt tun below about 700 Khz or so. Posing the question on the Xtal Set Societie's excellent discussion forum Rap'n Tap brought elightenment from Golfguru who wisely asked the length of my winding, pointing out that the inductance of the coil should be calculated from the total length of the windings, INCLUDING the bifilar primary. Running back to Professor Coyle with a 3.27 inch length gave me 112 uH and a lower tuning range of 660 kH or so. So, "Mystery" solved...

The following is a final schematic of the set and photos of the set as it exists. I listen to it most evenings as I work.

cap, all displayed on a breadboard box with wireing hidden inside.

The risk here was inexperience and it certainly came home! My 18 AWG wire turns per inch were rather different from values assumed in the "Professor Coyle" spreadsheet, both because the sheet assumes bare wire and because my ability to close wind is not that great! My first attempt was for experience, but not for getting a useful coil. Rethinking and adjusting allowed success, almost, on the second attempt and I got 46 out of a planned 48 turns on the main coil. Assembly was difficult but in the end I had a lovely set that wouldn't bring in anything! Well, almost nothing, some weak interfering stations at the cap's full-open position. My first photo is of this incarnation.

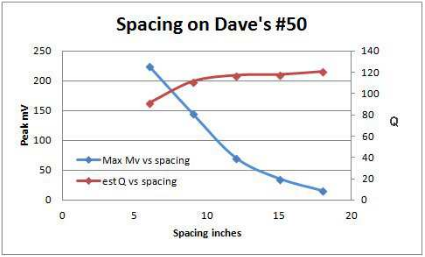


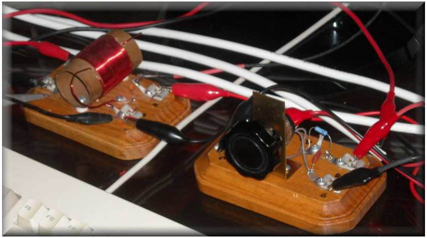
In figure 5 above I have attempted to cast Dave’s measurements into something similar to what I am doing, which is looking at the -3db BW and Q at 1100khz. I finally produced the above spreadsheet where I simply smoothed the data for the 1000khz case and estimated the bandwidth at -3dB. This makes a LOT of assumptions of course. Mostly I assume that the +-10khz measurements are well above the resonance skirt so my smooth curve is not unreasonable.

The #50 set then appears to have, at 1000khz, a -3db bandwidth of around 8-11khz depending on diode and/or spacing between the tank and antenna unit giving loaded Q's of 91-125. These numbers fall in the range of what my own data lead me to expect. Ken Kuhn's page on Resonant Circuit suggests the "typical" QL at 1Mhz ranges between 20 and 100 and Dave’s #50 set is certainly beating the best of that.

In the final figure 6 I have taken my estimated results above and looked at how Q and peak voltage (assuming constant conditions other than the spacing between the antenna and detector units so this ought to reflect power as well). It is quite apparent that the set is rapidly losing output power while Q improvements are flattening out as the spacing between tank and antenna tuner grows to 18 inches. It would appear that a -3db loaded Q of 125 is near the limit of what can be expected in a crystal set.

Figure 6.



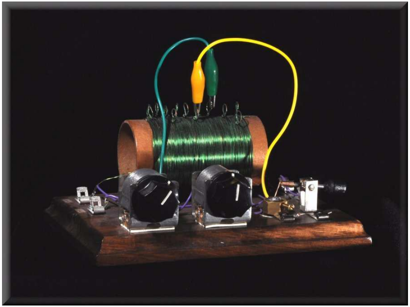


My first homemade, A Mystery Set

http://www.lessmiths.com/~kjsmith/crystal/mystery.shtml

Having made the Dunwoody and experienced the thrill of listening to the local broadcasts on a radio of my own, unpowered save for what the stations themselves provide, I was thoroughly hooked on crystal radio. I hit the web for all I could find, which is considerable. My many thanks to all of you who have provided such useful and informative pages. I categorize my effort along two axes, 1) finding and reading sites with background theory and advice on crystal radio, and 2) sites of crystal radio builders to know what is possible and find inspiration. I was determined to produce a set of my own from scratch. Of all the possibilities, and there are SO MANY, I soon settled on the Mystery Set as an interesting and challenging goal. I have the impression that many, perhaps most of the experienced builders who make their presence felt on the web have built this, or modifications of this set. A worthy place to start, worthy company.

My intent, after studying so many variations of this set was to settle on the original set as published in the 1932 Brisbane Sunday Mail. If I can do well, then only can I consider modifications. My plan was to take the basic circuit, but otherwise use my own forms and wire, calculating appropriate inductor dimentions and winding specific for my needs. I sought a square coil with large dimentions, 8cm mailing tube wound with 18 AWG magnet wire, switchable detector between a diode and homebrew, and a lovely vintage 500pF



My library of Crystal Radio Hookups and theory...
http://www.lessmiths.com/~kjsmith/crystal/catalog.shtml

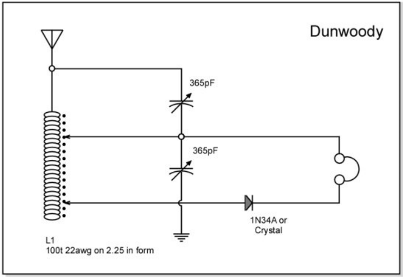
This section of my page started out as a place to put my compilation of crystal radio circuits. That compilation became a catalog featuring circuit diagrams hand-drawn by myself from various sources (as indicated on each page, see catalog reference). When I first entered the crystal radio hobby, I was amazed and more than a bit intimidated by the sheer variety of circuit possibilities. I began to make my own circuit drawings in order to get a handle on this in addition to finding interesting circuits to construct myself.

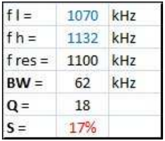
To organize the circuits from fairly easy to rather complicated, I put together a simple classification based on the number of Inductors and Tuning Capacitors in each circuit and a few of their main distinguishing features. Better classifications may exist, but this works well enough for my purpose. A legend follows so anyone may break the code. The catalog provides only minimal information about each circuit. Although an experienced builder may make the calculations to build a radio from the data provided, I mostly intend this for information only. I highly recommend if you wish build a set to consult the original reference.

Later as my experience and familiarity with crystal radio has grown, and after having built and tested a certain number of sets, more detailed and technical information has become necessary. Scouring the web has turfed up an amazing number of extremely well written and helpful web resources. While the number of excellent web sites is large, there have been a certain few that I found myself returning to time and again. From these I would print out large sections and read carefully, scribbling notes on the side, generating more questions and learning, learning, always learning.

Eventually I began to assemble what were, to me, the most useful and informative pages into a handy book format. I decided to print the darned thing out to keep as a sort of Crystal Radio Handbook, something to take with me on the go, or just to read on the couch. I am NOT a "kindle" type.. The project was no trivial thing. I knew what I wanted, but casting everything into a common (more or less) format, organizing things, formatting figures, etc, it was a lot of work. For my handbooks, a glance at the table of contents shows a book organized to lead the reader along the path I followed. The authors are many and I wish to thank 10,000 times all the people who have contributed so much to this hobby on the web. My apologies if I did not choose your pages for the book, the choices of what to include and what to leave out was purely my own. The final Handbooks, there are three now, I feel represent university-level material from advanced introductory to university senior / graduate presentations on Crystal Radio. Published handbooks on crystal radio are traditionally directed primarily to the "boy scientist" adolescent, introductory in nature. I hope this these handbooks fill a gap rather than pander.

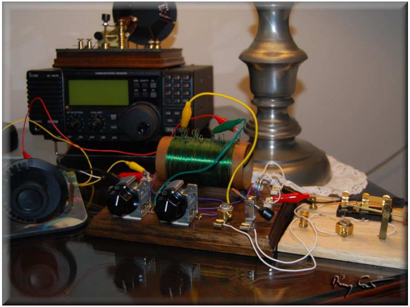
Finally, to help as reference, I eventually formatted two particularly interesting web pages as complete volumes in themselves. Ben Tongue's pages are essential reading for the serious hobbiest, even if over my head, (read.. waaaaaaay over my head). At nearly 400 pages, I have broken it into two volumes. Kenneth Khun's web book is just great, technical, but not overly, well explained as one would expect from a professor. Thanks for your efforts and for all those others whose pages I missed.





f l =	1070	kHz
f h =	1132	kHz
f res =	1100	kHz
BW =	62	kHz
Q =	18	
S =	17%	

Performance summary of my Dunwoody is so so with a set Q (loaded) of 18 but my sensitivity calculation is 17%, not so great. This may be all that can be wrung out of a single-coil radio, who knows? Most of my radio's have higher sensitivity so this set definitely benefits from my audio amplifier.



Circuit schematic for the set.

I intend these documents to be printed on double-side letter paper, folded over or cut in half and then bound. The foldbook paging system in the document only makes sense when this is done.

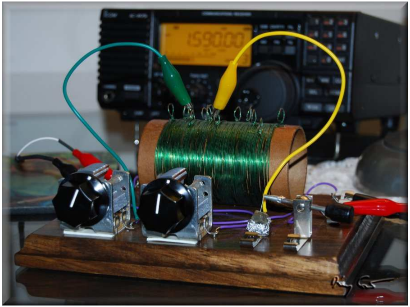
The radio now has a NOS Philmore crystal detector stand. In this photo I am testing a Pyrite crystal sitting on a crumpled aluminum foil bed, successfully detecting 1590 Khz locally here in Houston. In the background is my trusty Icon R75 giving me the straight poop on what station I am listening to. I was never really happy with the Philmore crystal holder though, it had to be improved.

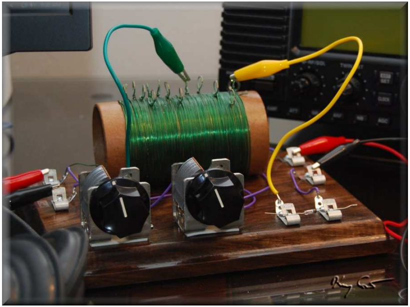


Current configuration on the Dunwoody now sporting a good brass crystal cup with set screw, also I have lifted the coil off the wood base with 1/4" standoffs. I am not sure how much of a difference that made, but seems good practice. This photo of the set taken while prototyping a homebrew detector stand of my own. I figured if I was to become a radio builder, I would need master the detector. I am a geologost so no radio is a crystal radio without a crystal, I mean, an actual crystal!

me back to my roots as a minerologist as well. In my fun I have subsequently learned to pot my own crystal detectors in woods metal, and tested a number of minerals as detectors, though in no systematic way. I did immediately notice that Galena and Pyrite, the most frequently cited minerals as detectors, are metallic sulfides so I have acquired additional samples of Stibnite, Molybdnite, Argentite, and Acanthite, only successful with the Molybinite. Seems a high degree of symmetry is needed as well.

The following photos are of the radio as originally constructed and a couple morphs as I learned to love this great hobby.

My Dunwoody in its original configuration as per the kit instructions. Clearly seen is my first-ever attempt at winding a coil, first attempt at taps in said coil, and a fine radio just the same.

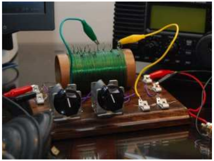


CHAPTER II

Radios I have built with my own little mitts…

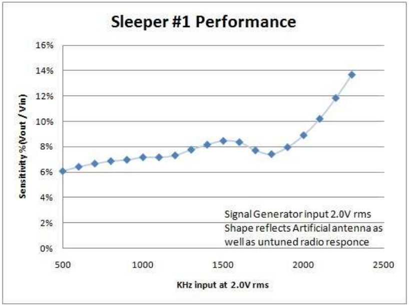
Dunwoody, a kit from Borden Radio right here in Houston

http://www.lessmiths.com/~kjsmith/crystal/dunwoody.shtml



My first real intro to this fascinating world of crystal radio came with a set I purchased on Ebay from Borden Radio Company, Lance Borden. Lance is an engineer at NASA and radio amateur with a business selling crystal radio's and parts. When I first ordered my kit he was very helpful and encouraged me quite a lot. I appreciate the well-designed radio as much as his help in my introduction. The radio itself is a single-tuned set with dual 365 caps tuning on the antenna and detector sides of the single coil. The coil features numerous taps, a concept I was quite unfamiliar with and curious about when I first considered the set for purchase. I figured I had much to learn and the set seems a good and serious way to begin.

The Dunwoody comes with a 1N34A diode detector, two 365 variable capacitors, fahnestock clips, a sturdy cardboard coil form and magnet wire to make the inductor. The included instructions are clear and easy to follow. One item not included or part of the radio is a crystal detector, but the instructions give a hint by stating that the spacing for the germanium detector are the same as for a Philmore detector. That sent me to the web and introduced me to the crystal in crystal radio. I thoroughly had the bug by this time as I searched for, and eventually acquired a Philmore detector and crystal. In fact the galena crystal is remarkably hot and often performs every bit, in my opinion, as well as my germanium diode. This has led

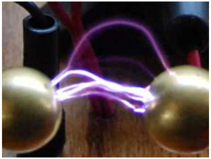


Hooking parallel configuration to my signal generator can give an idea of the performance of the radio across the spectrum. I measured the mV output in 100 KHz increments from 500 to 2300 KHz. Across the broadcast band the set has faitly flat responce with a slight tendancy to resonance about 1500 KHz and then increasing sensitivity from 1900 KHz on up. Keep in mind that the set is hooked to a dummy antenna rather than my actual long wire. Still this gives an idea of the overall untuned nature of the circuit.

When I hook in a series configuraiton I am unable to get a measurement, only 0V DC output. I am working on why this may be the case. Drives me nuts.

A Spark-Gap Transmitter

http://www.lessmiths.com/~kjsmith/crystal/spark.shtml



Why a spark-gap transmitter? And why here on a crystal radio page? Well, the second question I'll answer first as it is easiest. The transmitter is a vintage technology device that is no longer current in the modern world and so fits thematically with the purpose of my crystal radio page. The first Question is more interesting, why build it? In late 2009 my elder brother, founder and owner of Northwest Research Engineering, LLC., in Seattle, challenged me to construct a spark-gap transmitter. He enjoyed seeing my vintage-style crystal sets and we enjoyed discussing the early history of radio together. So, it seemed a logical step to progress in this direction. Additionally, as his work is in cutting edge ionospheric research, he has little opportunity to study such retro technologies up close and personal.

> DISCLAIMER:
>
> I am not a licensed radio-amateur and in any case a spark-gap transmitter is not legal to use in the United States. As such, this project was taken on as a technology-demonstration exercise only and is not intended for actual use. Such use is not permitted. Nor is this page intended to promote the construction and use of such transmitters by others. I DO give detail on the construction and theory of the transmitter in order to better understand and appreciate the technologies used at the dawn of the modern wireless era.

The concept behind the project is to build an operating spark-gap transmitter using technology as close as possible to that used at the turn of the 20th century. Technology that would be recognizable to Marconi or Fleming. This meant no chips, no transistors, no diodes, (OK, a galena and cat's whisker is technically a diode, but you know what I mean...) no solid-state. It does not mean using vintage components as these are for the most part unobtainable and/or prohibitively expensive. With each component new or homebrew the question is: would Fleming recognize this? Sometimes I needed to stretch things somewhat, especially concerning the relays, but still I believe I have remained true to this original goal.

The transmitter was conceived as two modules, a power module and an oscillation module. Size constraints forced me to break the oscillation module further into two breadboards, one for the variable HV capacitance and the other for the oscillation transformer. The power module is the most complex piece having on it the induction coil, interrupter, capacitor, and the spark gap itself. To keep this page length manageable and allow enough space to give a good description of each component, its theory and function, I have broken the descriptions into separate links below.

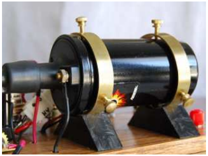
Induction Coil

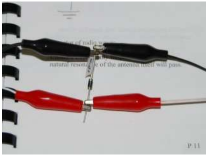


Marconi's first successful radio employed an induction coil as its main energy source. Other methods were quickly adopted that were more efficient and more powerful, but the reliable induction coil remained common throughout most of the early period of radio. Fleming describes a typical "10-inch" coil used for radio work in his day. By 10 inches, he refers to the length of spark obtainable with the coil. These coils are large and today mostly unobtainable except as specialty reproductions at outlandish prices. Fortunately the venerable induction coil remains in manufacture as the common (increasingly uncommon unfortunately) canister ignition coil found in most cars built through the 1970's. In Fleming's terms such a coil might be called a "1-inch" coil, woefully inadequate for transmitting messages to China perhaps, but ideal for this project. Standard coils generate up to about 30,000 volts and "sport" coils can put up to 45,000 volts.

When I first began researching this project I was surprised by the difficulty in finding useful technical specifications for ignition coils of various manufacture, or even of knowing what constituted a "good" versus a "bad" spec when such specs were found. What little information is generally published includes the maximum voltage naturally, often the secondary resistance, sometimes the primary resistance and the turns ratio, (ratio of primary to secondary windings). At first look there doesn’t seem to be much correlation between voltage and turns ratio or

Sleeper #1

http://www.lessmiths.com/~kjsmith/crystal/sleeper.shtml

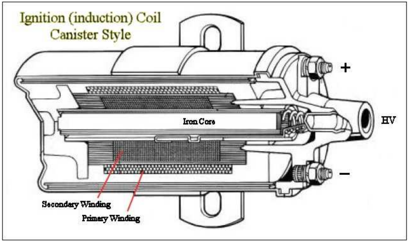


OK, this is a bit of a cheap shot for a radio, but.. it IS a radio!

It is always interesting to get down to bare essentials, to do the absolute minimum and still get a working instrument. It is not for nothing that MB Sleeper included a circuit diagram for this hookup, it is a functionning radio. This circuit is essentially a detector of radio broadcast energy. It has no tuneing functionality. Resonance is extremely broad although weakly peaking as determined by the impedence and capacitance of the antenna itself. In part my idea is to see if it is possible to determine this peak region.
I present the set photo with a 1N5819 Schottky diode but it works well with virtually any diode, only the sensitivity changes. I even tried a Zenner diode but had to attach the Radio Shack mini-amp and crank it up. Still, it worked ok. So, more to come..

even resistances. It took a lot of research to learn the needed theory behind Kettering ignition coils and much of what is found on the web is inadequate, oversimplified, poorly founded theoretically, or downright wrong. I will try here to explain in moderate detail how the Kettering Ignition System works, the theory, and therefore how the various components (windings, primary, secondary, capacitor, resistances, etc) work together. With the right theoretical underpinnings, the specs do make a lot of sense.

Induction coils operate by storing large amounts of energy in the form of strong magnetic fields. As currents pass through the windings their electric fields generate magnetic fields, and fields in one coil induce fields in the other, primary and secondary. As long as a current is maintained in one winding its magnetic field is sustained and a corresponding field is sustained in the second winding. Conversely, moving the coil through a magnetic field or removing the field entirely will generate an electric field, (measured as voltage) in the coil. The ratio of turns between the windings determines the ratio of voltages between the coils. Although the input voltage to the primary coil is small, only 12V for a car battery, it has a large current and a great deal of magnetic energy will be stored in the primary coil. By shutting off the primary voltage source the magnetic field of the primary collapses. As this magnetic field collapses it cuts the secondary coil generating a very high voltage output. The rate of field collapse (dB/dt) determines the strength of the voltage output of the secondary. This high voltage output spikes only when the primary current is shut off causing the field collapse. Coils therefore require an interrupter to repeatedly switch the current to the primary on and off. The trick is to select materials with needed properties to achieve the results wanted. The Kettering Ignition system use in this project is described next.



Ignition (induction) Coil
Canister Style
+
HV
Iron Core
−
Secondary Winding
Primary Winding

The Kettering ignition system consists of a 12v battery (the source of emf), an induction coil, a capacitor, and a switch of some sort, (points, relay, vibrator etc..) in a car its points. For the coil the primary and secondary are wound in series and connected together inside the canister. The coil has inductance and impedance/resistance. As the system has LRC, (L = Inductance, R = Resistance, C = Capacitance) the circuit has a resonant frequency and this frequency determines the unit time period "dt" in the equation V = L di/dt. Even without the capacitor there remains some distributed capacitance in the coil and so opening the points will never instantaneously collapse the magnetic field, but it will be extremely fast just the same. The field is maintained by the current from the battery to ground, opening the points removes the ground and stops the current.

As the circuit has a more or less fixed L and R from whatever coil you have available, you can only vary C by choosing the capacitor carefully. For cars, this typically means a capacitance

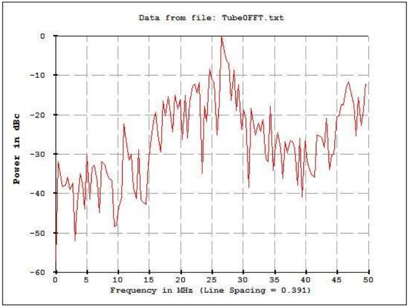
Does it work? What does it sound like on an AM radio? I recorded the above plot off a small AM radio tuned to the top of the broadcast band. Plenty of signal to go around, I understand why these transmitters are no longer allowed to operate! I give you a couple CQ's and an SSS in commemoration of Marconi's first transatlantic radio reception on December 12, 1901. Fleming designed the transmitter power station at Poldhu for the transmission.

CQCQ Yes... it really IS a transmitter..
SSS

73



If I can get my arms around the frequency and learn to control this, I see this as an excellent gap for my set. But, would Professor Fleming recognize this? I must fall back to my vacuum relay justification and restate that Fleming, as the inventor of the vacuum tube, was no stranger to placing elements inside a vacuum. He would certainly recognize this.

****

Transmits:

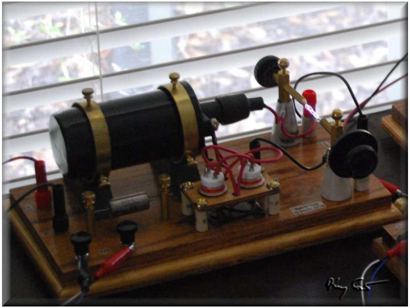
in the 0.1 to 0.2uF range. This capacitance gives a resonant frequency such that the dt will deliver a 30kv jolt to the plugs from the secondary of the coil within the period allowed by the engine timing.

A smaller dt (shorter unit time) delivers a higher secondary V (do the math) but standard coils are not designed for this and the internal insulation will probably not handle the tension. Additionally, the primary also delivers a voltage back to the switch/points/relay. A smaller dt will also result in a higher V off the primary. Of more importance, the smaller dt means that the back emf hits the points early before they have had much time to open. Either the higher V and/or the early arrival will cause arcing at the points. Arcing at the points creates a low resistivity path to ground and leaks the power away from the coil and so the secondary will also not deliver much V to the gap.

Conversely, a dt too long will slow the rate of charging and prevent the coil from being charged sufficiently in the time available (dwell time). The field collapse will be slower lowering the voltage out of the secondary, V = L di/dt. A smaller capacitance means higher frequency/smaller dt and vice versa.

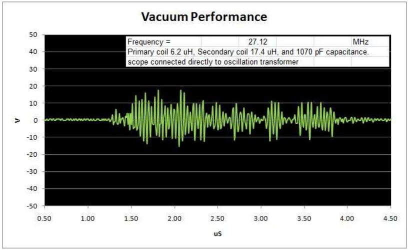
As dt is determined by the resonance of the LRC circuit, the variable you have to work with is generally the choice of capacitor value. Modern high performance coils also factor in. they have lower R (resistance) and lower L (inductance). lower L hurts because the energy stored in the coil is as follows: Energy = 1/2 LI^2. Reducing L lowers the stored energy. lower current (I) also lowers stored energy. Lower R increases the amount of current flow per unit time as well as increasing the frequency of the resonant circuit. Larger di and smaller dt means a much larger V. High performance coils are designed to deliver 45kv instead of 30kv and must have the insulation appropriate to this. The "performance" of these coils comes from two favorable factors, the high voltage assures sparking in high compression and the small dt allows sparking at high RPM's in 8 cylinder engines. That is, it's the small dt that allows sparking at very fast cycle times. They still have roughly 100:1 turns ratio.

Photo of the induction coil / ignition coil mounted horizontally on the power breadboard. Other components seen include the interrupter relays, the capacitor used to determine the coil resonant frequency, and the active spark gap. The thing really works!



The following are a few easy specs on some popular ignition coils, only a small sampling:

oxidized. This results in an uneven and "messy" spark. More importantly, I suspect that there is a LOT of arcing taking place at the gap as well. Arcing is a continuing current that effectively shorts the closed circuit to ground. This would explain why the audio-frequency coil oscillations are present even when the sparking is present. The vacuum gap prevents oxidation and produces a clean spark with every pulse. The electrodes are also made of either zinc or tungston or some other refractory metal. The lesson to be learned, make your electrodes of something more durable than brass and get some steel wool to FREQUENTLY clean the tips!



circuits have different wavelengths and so will set in motion a variety of unwanted harmonics. Presumably, with an actual antenna close to the design specs the transmitter will perform flawlessly!

****

The above analyses are presented with the transmitter and gap working in their "normal" operation mode. You will recall in my section on the spark gap that I also have tested a UHF vacuum tube spark gap. The following plots give some early interesting results needing presentation here. The RF oscillogram is quite typical of what this spark produces. You will immediately notice that instead of an RF pulse consisting of several distinct phases as before, this gap produces very clean almost pure HF tones with varying amplitude in the 27MHz range. These two differences, unphased tone and high frequency need explaining. For the difference in frequency I am really at a theoretical loss, all the formula I have tell me that the frequency results from inductance and capacitance, two parameters that did not change. I can only speculate that, as the spark resistance ought to be significantly lower in the vacuum gap, this may be the cause. More testing and more reading needed!

As for the tone itself, again I need to speculate and hypothize. If you look again at the initial audio-frequency oscillogram, you note the obvious induction coil audio oscillations as well as the initial spark. Normally these oscillations should not be seen unless the electrodes are separated far enough to prevent sparking. Initially in my testing this was the case, but with time the coil oscillations became a normal part of my responce. Additionally, with time I have had to adjust the electrodes ever closer to get consistant sparking, thus the frustration. I hypothize that the electrodes themselves are getting quite

PerTronix 45011: V max = 45000 V, P res = 0.6 ohm, S res = 8.6 ohm, P ind = 5.5 mH
Mallory 29217: V max = 58000 V, P res = 1.4 ohm, S res = 10.0 ohm, P ind = 6.6 mH
MSD 8202: V max = 45000 V, P res = 0.7 ohm, S res = 5.2 ohm, P ind = 8.0 mH
Taylor 718203: V max = 45000 V, P res = 0.7 ohm, S res = 4.7 ohm, P ind = 8.0 mH

For my project I have used the PerTronix coil above although I imagine most will do nicely. The Kettering discussion, appropriately placed here in the Induction Coil write-up, is needed understanding in the next section on the Coil Interrupter selection.

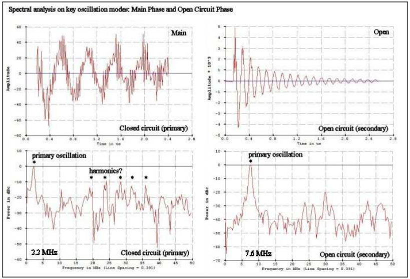
Coil Interrupter

In order to function properly an induction coil requires an interrupter circuit. The high-voltage output of the secondary winding results from the magnetic field collapse of the primary when its current source is interrupted. A single interruption will cause a single HV spike and thus a single spark. Repeated sparks require repeated charging and closings of the primary winding. For my project I was seeking a pulse-rate some 60Hz or better to give an audible tone at the receiver. Too rapid though and the induction coil will not have enough time to charge between cycles. Putting things into automotive terms, a 4-cylendar engine idling at 750 rpm must cycle the coil every 40mS, or 25Hz, no problem. For an 8-cylendar engine running at 2500 rpm you are down to 6 mS cycling (170Hz) and many coils are unable to work well at such rates. High performance coils are intended work well even at such high rates. For the transmitter I feel a cycle frequency between 60 and 100Hz would be ideal.

It would be lovely if cycle timing were the only constraint, general purpose relays typically run around 60Hz. Indeed this was my initial design, woe is me. Another concern the interrupter needs to deal with is the presence of a back emf from the induction coil primary winding. With a 100:1 turns ratio, a coil that sends a 45kV pulse out the secondary will also send back to the interrupter a 450V pulse. Small general purpose relay contactors remain rather close together even at their widest separation and so are prone to arcing with modest

Open circuit:
Secondary coil = 17.4 uH (L1)
Distributed inductance = 0 uH (Lo) (no distributed inductance)
Distributed capacitance = 25 pF (Co) (Scope probe in X10 position)
Wavelength = 59.6 sqrt((L1 + La)*Co)
Wavelength = 39m = 7.63 MHz

The two following plots give spectral analyses of the oscillations in the closed and open circuits.



This analysis gives a pretty close prediction to the values actually found on the testing and gives confidance that things are behaving as per theory. Other frequencies noted are harmonics and/or interference between the open and closed circuits. The original design was set so that both open and closed circuits resonated together at 120m. Under test the two

Right about now the observant reader must have noted that the frequencies measured, 2.11 MHz on the closed circuit, and 7.66 MHz on the open circuit, (and variations in-between) do not compare well with the design frequency desired. This certainly needs to be looked at. Recall my original design was for 2.5 MHz on both circuits with the following parameters:

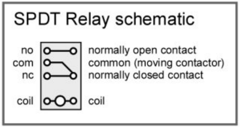
Closed circuit:
Primary coil = 2 uH
Capacitance = 2000 pF
Wavelength = 1884 * sqrt(L*C) = 119m = 2.52 MHz

Open circuit:
Secondary coil = 20 uH (L1)
Distributed inductance = 20 uH (Lo) La=Lo/3 = 6.65 uH
Distributed capacitance = 150 pF (Co)
Wavelength = 59.6 sqrt((L1 + La)*Co) = 121m = 2.48 MHz
Wavelength = 1884 * sqrt(L*C) = 121m = 2.49 MHz

Under testing conditions I have made some significant changes to the above. Specifically, the lumped inductance and capacitance are changed to P = 6.2uH (closed circuit), S = 17.4uH (open circuit), and the capacitance = 1070pF (closed circuit). Also, the design assumed a "generic" antenna with distributed values La = 6.65uH and Co = 154pF. Under test there is no antenna and the scope probe gives about 25pF capacitance and no inductance. Substituting the test values provides the following analysis:

Closed circuit:
Primary coil = 6.2 uH
Capacitance = 1070 pF
Wavelength = 1884 * sqrt(L*C) = 153m = 1.96 MHz

voltages. When I first hooked up my relay I got modest sparking from the gap and contact arcing that was quickly burning up the relay. It was my belief that the capacitor was there to slow the process and allow time for the relay contacts to separate before the back emf hit. I tried capacitors of increasingly high capacitance, they did not cure the problem. It was time to hit books and work the test bench.



What follows was a better understanding of relays in general, and SPDT relays wired in a buzzer configuration in particular. An SPDT relay has a common contactor set between two posts. The contactor has a spring which keeps it in contact with one of the posts, the "Normally Closed" (NC) position. The other post thus represents the "Normally Open" (NO) position. The relay also contains a small coil that, when energized will push the contactor towards the NO position and so breaking the NC contact. In a buzzer configuration, breaking the NC contact also de-energizes the relay coil so there will be no more push towards the NO post. The contactor will use what little momentum it has to oppose the spring and move to the NO position. In reality this momentum is not sufficient and so no contact with the NO post is ever made. This is why one always uses the NC post with the SPDT buzzer relay. A further negative consequence of this is that the contactor never separates far from the NC post. The close proximity allows breakdown of the dielectric potential of the air between the posts and arcing to occur.

Solutions to this arcing problem come in two flavors, the dielectric and the contactor separation. One solution used in high power relays is to enclose the contactors in a high-dielectric oil to suppress arcing. This is very effective but the fluid is difficult to work with, expensive, and it slows the contact frequency greatly. Recall that I am seeking at least a 60Hz contact frequency. Another way is to place the contactors in a vacuum. While not as good a dielectric as oil, it is significantly better than air and has the advantages of being easy to work with and maintains high frequency operation. Several companies manufacture vacuum relays and, while expensive, this is the route I chose. Note: there is of course a third solution to abandon relays and go solid state. This is fine if all you desire is cool sparks, but it is not in my directive.

Even vacuum relays when wired as a buzzer have the contact separation problem. If the contactors remain very close then arcing can still cause trouble. The method to force the contactor to move to the fully open as well as fully closed position, allowing maximum separation, is to wire two relays in series. The resulting contact frequency (duty cycle) will be half that of a single relay. Happily the vacuum relays operate at a frequency of about 200-240Hz. That provides a 100-120Hz operation in a two-relay configuration, very sweet. Additionally, the two-relay output consists of a nice square-wave signal bringing joy to the professional radio engineer. I know this because the circuit configuration was suggested to me by my clever elder radio engineer brother. Fei chang gan xie! Of course, this solution doubles the expense of an already expensive relay. I have tried the configuration with general purpose relays and find the resulting 30Hz operation unacceptably slow.

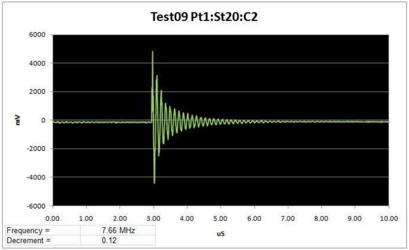
---

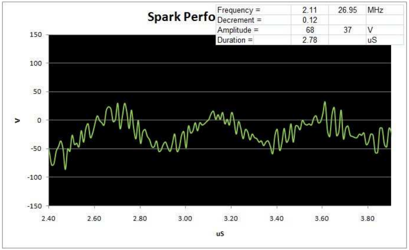
frequency. High decrements, (in the 1920's a spark-gap transmitter was required by law to keep a decrement of 0.2 or below) indicate a poorly engineered / poorly operated station. Calculations for the wave decrement as follows:

Decrement = 1/n ln (Xo/Xn) where Xo is the amplitude of one wave and Xn is the amplitude of another wave n periods following.

Damping Ratio = 1/sqrt(1+(2pi/D)^2) where pi = 3.14 and D is the decrement from above.

A particularly nice example of an isolated fully-quenched oscillation follows. I assume in this event that enough energy remained present in the closed circuit to allow an occasional isolated single spark to jump the gap. Such a spark produces a nice ring in the open circuit without the complexity associated with the main sparking from the induction coil. This plot shows the open circuit ringing nicely at 7.66 MHz frequency with an acceptable 0.12 decrement.





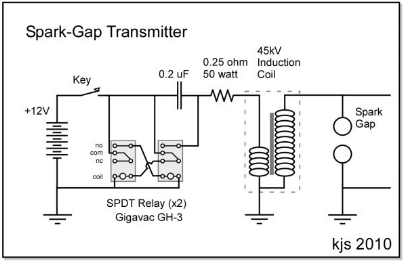
Frequency =	2.11	26.95	MHz
Decrement =	0.12		
Amplitude =	68	37	V
Duration =	2.78		uS

Finally, when the energy loss finally quenches the sparking at the gap, the open, secondary circuit then can freely oscillate, here with a frequency of 10.76 MHz and lasting some 3.3 uS. This last phase is the desired transmission frequency and the open circuit normally oscillates into the antenna. Decrement on this last phase is an excellent 0.04. Early spark gap transmitters struggled to reduce or eliminate the initial two phases of the event with quenched gaps.

Why is decrement important? Most RF damping in a spark-gap transmitter results from interference between oscillations in the open and closed circuits of the oscillation transformer. When these waves interfere two separate wave energy peaks are radiated from the antenna causing loss of signal strength at the desired frequency and adjacent channel interference. A good spark-gap transmitter should quench the closed circuit as quickly as possible after the energy is transferred to the open antenna circuit. Once quenched the open antenna can resonate at its natural frequency. Lacking quenching as with my transmitter, the oscillation transformer needs to be carefully tuned to resonance and loosely coupled to radiate at a single

One final and somewhat late note concerning the vacuum relays. These relays, (Gigavac GH-3 or Kilovac HC-3) are load-switching devices designed to operate to 18 amps. The Pertronix coil on the other hand runs nicely at a cool 20 amps (12 V and 6 ohm, Ohm's Law here). The duty cycle is plenty slow enough to allow a longer charging time so all those amps shouldn't really be needed. I have added a 0.25 ohm ballast to the circuit to lower the current to about 14 ohms. Those cute little relays are very expensive and I have already damanged (temporarily) one of them by pushing 20 amps through. With the ballast I DO find the spark power, measured in terms of brightness, noise level, and max length is diminished somewhat, such a pity.

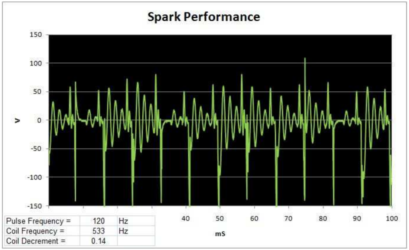
So, would Fleming recognize this? It is where I push the boundaries as I doubt that vacuum relays existed in his time. Still, relay action was well understood in Fleming's day. As for enclosing them in a vacuum? Well, I defend myself by stating that Fleming himself invented the vacuum diode. Enclosing electrical devices into vacuum bulbs was not a new idea even then. So, while the vacuum relay may not have existed, relays themselves did and Fleming would have been comfortable with the vacuum technology. I think...



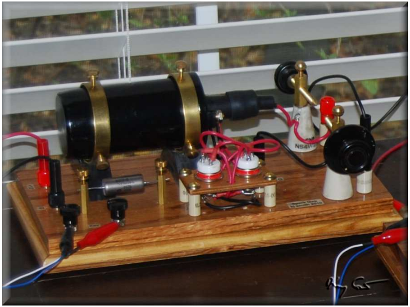
Circuit diagram of the power module indicating the wiring concept for the two-relay solution. And finally, a photo of the set with the two relays in position and ready to go.

	Precurser	main		tail	
Frequency =	1.01	2.11	26.95	10.76	MHz
Decrement =		0.12		0.04	
Amplitude =	520+	68	37	19	V
Duration =	0.27	2.78	uS	3.3	uS +

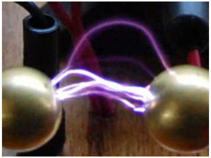
Zooming in to the radio frequency world the above plot shows the radio frequency wave in some considerable detail. This plot indicates that the oscillations given off from a spark gap are anything but pretty. The complexity results from the ringing going through several phases with the closed and open circuits, and induction coil each having their imprint. The initial (precursor) phase of the event, lasting here about 0.27 uS is the high-amplitude energy (upwards of 520+ V) of the spark as the induction coil pours its energy directly into the circuit at the gap. This is followed by the main phase, a complex 68 V amplitude ringing lasting some 2.8 uS. The ringing consists of two combined waveforms, one, a high amplitude (68 V) 2.11 MHz wave with a second lower amplitude (37 V) high frequency 27 MHz wave superimposed. This phase results while the closed (primary) circuit still retains sufficient energy to cause sparks at the gap with each main oscillation. The higher frequency wave comes from the open circuit (secondary) inductively coupling to the closed. A detail look at the main phase seen below:



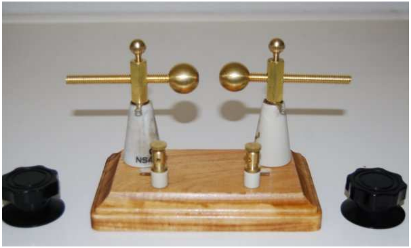
This first plot above shows the response at audio frequency. In the 100 mS plotted we see 11 pulses at 120 Hz frequency. This represents the pulse frequency of the dual relay system, two relays at a nominal 240 Hz each. Each pulse starts with a high amplitude spike associated with the spark discharge and followed by two to three damped oscillations with a frequency of 533 Hz. This oscillation is associated with the natural frequency of the induction coil itself. Damping of waves is a natural oscillation feature and is refered to as the wave Decrement. Decrement is the natural log (Log to the base e) of the amplitudes of any two successive peaks in the wave train. It results from the loss of energy in the circuit during the oscillation period. Energy is lost due to resistive heating, radiation of waved into space, and interference between oscillations in the primary and secondary oscillation circuits, especially where they are closely coupled. Where resonance is high the interference losses are minimized.



Spark Gap



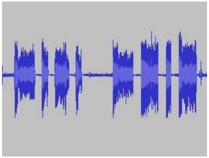
The heart of the system is the probably the simplest component, the spark gap itself. After all the required background theory for the induction coil and relay setup, this component was a walk in the park. Still I need note that my gap is not intended for serious duty and so does not require extra features such a cooling fins and/or etc. Below is an early mock-up of the gap, a simple set of 1/2" brass balls tapped for a 1/4" threaded brass support rod. The entire assembly set off the base with lovely tapered ceramic standoffs.



Early use of the spark gap, especially with a weak induction coil, showed up room for improvement. When sparking the

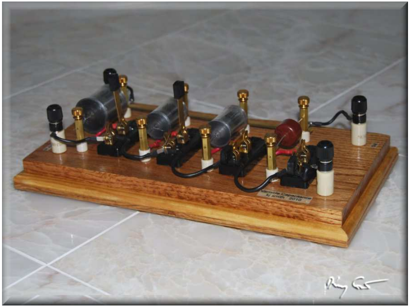
---

Performance Testing the Transmitter



If you build it, will it work? And how well? This page attempts in a preliminary manner to answer these questions and provide a first look at the performance through the eyes of an oscilloscope. It will take much testing and observation/head scratching before I ferret out all the phenomena present in the set. This is one of the objectives of the project, to study and learn about spark-gap technology. The plots below are a first look, some will raise more questions than answers, but that’s the fun!

All of the scope plots presented here are made with a single hookup to the scope. The scope probe was attached to the set antenna output of the oscillation secondary coil. Many other observation points remain to be made and observed and I will update this page accordingly when needed. I present observations of the three primary oscillation frequencies expected from the set: A) the pulse frequency from the relay, B) the resonant frequency of the induction coil + power capacitor, and C) radio frequency oscillations of the transmitter itself. So little work so far, so many questions remain!



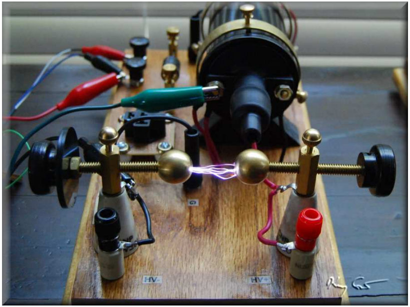
The capacitance module simply consists of high-tension modern capacitors switchable into or out of the circuit in parallel. The original intention, still in play, is to use Leyden Jars, but that is another matter. The four capacitors have values of 500, 1000, 1000, and 3000 pF giving plenty of combinations to choose from. Changing inductance is a matter of clipping to the coil at the right place. Finally, coupling the coils is a matter of sliding the secondary along rails into or out of the primary winding. The following photos give portraits of the two oscillation circuit modules.

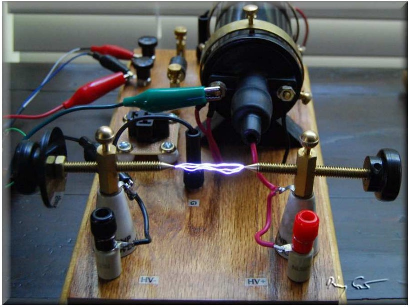
When one walks into a room, nothing quite says "Transmitter present!" like a big oscillation transformer!

---

brass balls build up an oxidation layer fairly quickly. This layer increases the dielectric between them and, especially when the voltage is marginal, (my first coil was old) the sparks had trouble to jump the gap. I needed to clean the balls frequently with steel wool. The 1/2" balls spread out the field flux over a small area. One improvement was to switch from a ball-gap to a gap between sharply pointed tips. The photos below show both configurations. The points concentrate the field and creates a higher potential. This makes it easier for the sparks to form. Switching between configurations is as easy as screwing on or off the balls which cover the pointed tips.

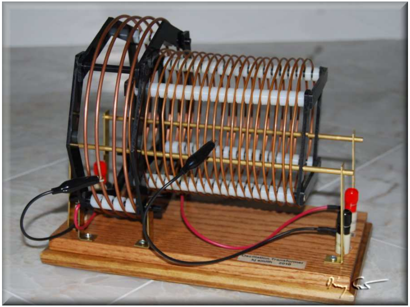
Adjustment of the gap length is easily accomplished by turning the end knobs of the threaded supports. Small top thumb-screws lock the posts at the desired position. CAUTION: Do NOT touch any metal components while the spark gap is in operation. Handle by the insulated knobs only.





In the photos above the sparks are being produced without any ballast resistance and are just over 2cm long. With the ballast I subsequently added to protect the vacuum relays, the spark power is lowered from 20 amps down to about 14 amps. The sparks obtained are smaller, about 1 to 1.5 cm. According to Fleming an induction coil capable of producing sparks up to 10 inches (25cm) in air will give a spark of 6-7 mm when connected to a load. I find with the tank circuit connected to the gap I need adjust the spark points very carefully and close, about half a mm or less to obtain consistant sparks. This can be a frustrating exercise. Air diaelectrics also have the problem of arcing when the air between the electrodes begins to ionize. A solution to this is to enclose the spark gap in a vacuum. It just so happens that occasional inexpensive vacuum spark gaps are listed on ebay. These tubes are intended for radar (UHF) applications and are rated in the few hundred volts range. As

The oscillation transformer design thus becomes a matter to choose coil lengths and diameters to give a range of values inclusive of Lsecondary = 20uH and Lprimary = 2uH. To make the transformer loosely coupled the secondary needs to slide within the primary. I chose the following parameters:
Primary: Diameter = 7", Length = 2.0", Turns = 4, uH = 3.81 max, 1/8" copper tubing
Secondary: Diameter = 5", Length = 6.0", Turns = 22, uH = 27.4 max, 1/16" copper tubing



to imagine an amateur inverted L antenna with about 20 uH distributed inductance and 150 pF distributed capacitance. As antennas are magical mystical things that nobody (meaning myself) really understands this appears entirely reasonable. In any case, the transmitter is tunable to bring it to proper resonance (hopefully) when attached to an actual antenna. These then are my fundamental design parameters:

Design frequency = 120m
Antenna Co = 150 pF
Antenna Lo = 20 uH (20000cms)
La = Lo/3 = 6.67 uH (6667cms)

L1 = Loading, or secondary coil = ?

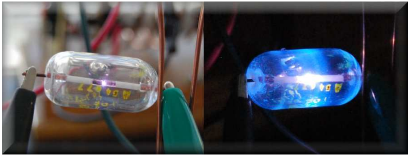
From Bucher:
Wavelength = 59.6 sqrt((L1+La)*Co)

Assuming a design frequency of 120m and solving the above equation for L1, I find:
L1 = 20 uH (20000cms)
20uH then is the value we wish for the oscillation transformer secondary winding.

For the primary winding we find in Bucher the following useful equations:
L = lambda^2 / 3550000 * C, and/or
C = lambda^2 / 3550000 * L

Therefore one starts with lambda = 120m and then either assume a capacitance or an inductance. For this project I found a good match with 2000 pF and 2 uH. To be safe both inductance and capacitance can be varied around these two design numbers.

my gap is tiny now, I felt this may be a good solution, or, alternatively I might have some fun blowing up a cool vacuum gap. The following photo shows that in fact the vacuum gap performs handsomely as a gap for my transmitter. The gap length is mercifully fixed at about a half mm and the low diaelectric allows good sparking with flat (rather than pointed) spark surfaces about 2mm in diameter. I certainly will experiment more with this kind of gap.

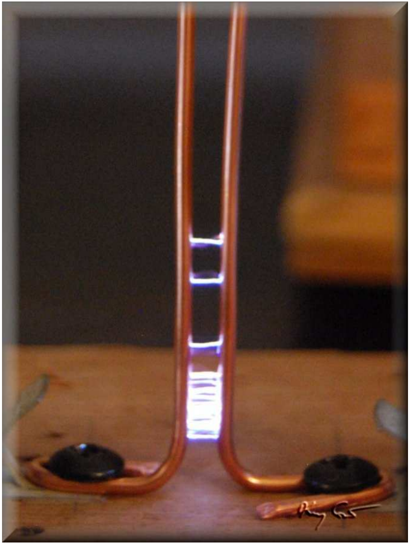


Thats'a some glow...!

****

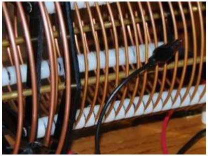
Other Sparks:

Of note, the gap itself need not remain strictly a set of pointed, flat, and/or round surfaces. Once you have a working High Voltage power supply, there are other gaps/toys waiting to be tried.
The photo below is a quick cobbled together Jacob's Ladder just to see: Will it work? The copper wire is not perfectly smooth nor can one adjust the spacing between the two verticals. Still, I can tell this will be a fun side trip with my HV power supply. Stay tuned for more.



Schazzam!!

Oscillation Circuits: HV Capacitance and Transformer



The oscillation circuit in the transmitter performs the twin functions of converting the spark's energy to trains of radio frequency oscillations and transferring them from the closed tank to the open antenna for transmission. Like any tank circuit the main components consist of capacitance and inductance, both variable in order to tune the circuit to the needed frequency. The closed circuit loosely couples to the open circuit to achieve the best resonance and lowest decrement. The design aspects of this section is where the radio theory begins and induction/relay theory ends, we are talking radio here now.

The design for the transmitter starts with a notional target transmission frequency and the design equations from two primary sources: Fleming, 1910, The Principals of Electric Wave Telegraphy and Telephony., and Bucher, 1920, The Wireless Experimenters Manual. Additionally it requires some estimate, guesstimate really, of the antenna distributed capacitance and inductance.

As the project is demonstration only, I have selected a frequency at the low end of the HF range just above the MW broadcast bands. The designs in the 1920's typically aimed at about 200m or 1.5 MHz. To keep my design close I chose 120m, or about 2.5MHz. It is a fairly quiet part of the spectrum. Keep in mind this is a notional project not intended for actual broadcast. I used charts and data presented in Bucher

Introduction:

The following catalog features circuit diagrams hand-drafted by myself from various sources (as indicated on each page, see catalog reference). When I first entered the crystal radio hobby, I was amazed and more than a bit intimidated by the sheer variety of circuit possibilities. I began to make my own circuit drawings in order to get a handle on this in addition to finding interesting circuits to construct myself.

To organize the circuits from fairly easy to rather complicated, I put together a simple classification based on the number of Inductors and Tuning Capacitors in each circuit and a few of their main distinguishing features, but this does not always feel right. Sets are arranged broadly by groups, single-tuned, variometers, double-tuned, etc. Better classifications may exist, but this works well enough for my purpose. A legend follows so anyone may break the code.

I provide only minimal information about each circuit. Although an experienced builder may make the calculations to build a radio from the data provided, I mostly intend this for information only. I highly recommend if you wish build a set to consult the original reference.

Please note that this compilation represents only a small fraction of the circuit possibilities in the world of crystal radio. Competition sets in particular can get very complex. I have tried to find a wide range of styles and ideas with examples from many circuit families. The reader is encouraged to pursue more on the web or via whatever sources are available.

Kevin Smith

Legend:

Coil

1, 2, 3+ number of coils
S = single winding selenoid
W = spiderweb, other non-selenoid
D = dual windings on one form
M = multiple windings on one form
C = co-wound, bifiliar
L = layered windings

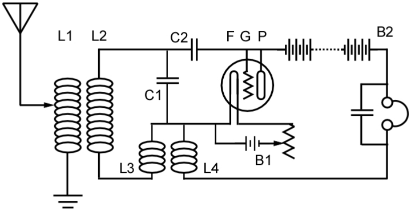
Capacitor

1, 2, 3+ number of capacitors
G = ganged

Features

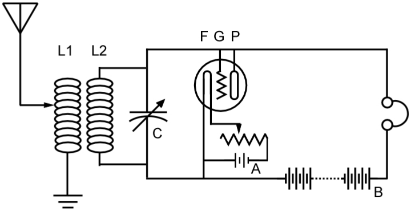
VM = variometer
VC = variocoupler
LC = loose coupler
FW = full wave receiver
LD = loading coils
CK = rf choke
CT = capacitively tuned
TG = tuggle tuning
TF = telefunken variation
SL = slider tuned
TC = tapped coils
LK = link coupling
LWT = linked wave trap
IWT = wave trap inductively coupled
MW = Medium Wave
LW = Long Wave
SEC = Selectivity Enhancement Circuit
B = Benny circuit

Armstrong Regenerative 12-1914



L1-2	coupled tuning circuit	
L3-4	feedback circuit (transformer)	
C1	tuning capacitor	
C2	circuit choke	
B1	A-battery	filament current
B2	B-battery	plate potential
Single triode vacuum (Audion) tube		
F	Filament	supplies electron current
G	Grid	control space charge around filament
P	Plate (Wing)	rectifier / oscillator

Armstrong Circuit
Audion Valve



Single Audion tube rectifies signal and provides amplification.

L1-2	Coupling coils
C	Tuning capacitor
A	Filament current
B	Supply of plate potential

Vacuum Tube elements

F	Filament	supplies electron current
G	Grid	control space charge around filament
P	Plate (Wing)	rectifier / oscillator

Unit prefix’s

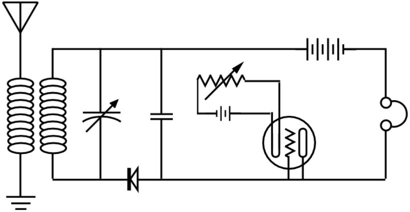
m	milli	10^-3
u	micro	10^-6
n	nano	10^-9
p	pico	10^-12

Old radio text notation
1 cm = 1 nH
1 mmf = 1 pF

Poole’s Quick Fix’s
Add a loading coil for short antennas
Add series capacitance for long antennas
Add coupling coil in front of tank
Tap antenna down on coil
Tap diode down on tank coil

To consider:
Add a Benny, even without matching transformer
Add SEC to unload diode
Add Bias to the detector

Pratt 1915   IRE v3, n2



Combined crystal detector and Audion amplifier circuit to test amplification on distant signals.

Fleming Valve

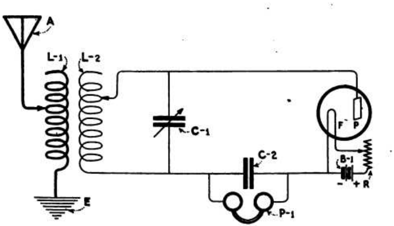


Figure 20a
Simple circuit for the two-electrode vacuum tube as an oscillation detector in radio telegraphy.

Rectification of signal with diode tube

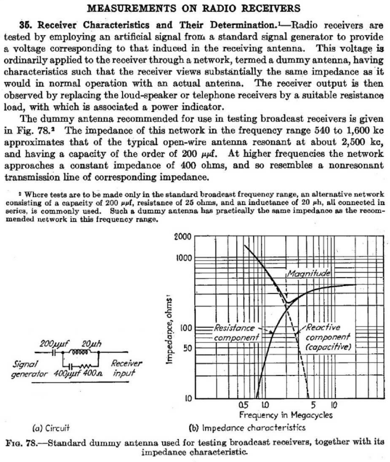
C2 =	0.01 uF

Hookup to measure crystal set performance. Connect dummy antenna between Signal generator and set, use load between set and DVM. Follow protocol of Lauter: http://www.oldradioworld.de/gollum/testing.htm

Note**:** Modification of the Load (pot) made to determine impedance match at output. kjs

Dummy Antenna



MEASUREMENTS ON RADIO RECEIVERS

35. Receiver Characteristics and Their Determination.[1]—Radio receivers are tested by employing an artificial signal from a standard signal generator to provide a voltage corresponding to that induced in the receiving antenna. This voltage is ordinarily applied to the receiver through a network, termed a dummy antenna, having characteristics such that the receiver views substantially the same impedance as it would in normal operation with an actual antenna. The receiver output is then observed by replacing the loud-speaker or telephone receivers by a suitable resistance load, with which is associated a power indicator.

The dummy antenna recommended for use in testing broadcast receivers is given in Fig. 78.[2] The impedance of this network in the frequency range 540 to 1,600 kc approximates that of the typical open-wire antenna resonant at about 2,500 kc, and having a capacity of the order of 200 μμf. At higher frequencies the network approaches a constant impedance of 400 ohms, and so resembles a nonresonant transmission line of corresponding impedance.

[2] Where tests are to be made only in the standard broadcast frequency range, an alternative network consisting of a capacity of 200 μμf, resistance of 25 ohms, and an inductance of 20 μh, all connected in series, is commonly used. Such a dummy antenna has practically the same impedance as the recommended network in this frequency range.

I have generally avoided including schematics and info concerning impedance matching transformers as I do not have much experience with them. The above general schematic I take from Ben Tongue’s article 01. Note that he includes a benny as a standard part of the transformer circuit.

The transformer provides a 16:1 transformation ratio between the typical 12k ohm phones and a tank Rd of around 192k ohms.

NOTES:

NOTES:

INTRODUCTION

The contents of this handbook consist of a number of web-based documents that provide significant and detailed insights into the design and theory of crystal radio. For the crystal set hobbyist, it is not sufficient to build from kits or merely follow published instructions or designs. It is important to gain deeper understanding of the theory behind the sets and learn from experienced members, to learn about the tricks and tips they employ to construct interesting and advanced sets. The web is a marvelous source of data and information. Many long-time crystal set builders have created dedicated sites to disseminate information and resources, to share their creations.

To further my understanding I have spent many long hours surfing the many excellent crystal radio websites. The wealth of information is outstanding, even a bit overwhelming at times. Pages range from simple to advanced, up to pages where one likely needs their EE degree to comprehend the material. When I first started I spent time on the basic web pages, but as I grew comfortable and began to consider more advanced features for my sets, I spent ever more time on more advanced web pages. Whenever I found material especially well presented and useful, I would print it out into notebooks and study for hours at a time. With time I came to find that within the large number of web resources available, there exists a canon of sites particularly well suited for study. While my personal needs and tastes ultimately dictate those pages I find useful, I do believe that these pages are the best of the lot.

In this booklet I have taken the sections that I spend most time studying and have arranged them into sequence from basic theory and design considerations to more advanced material on particular aspects of the hobby. Finally I include several sites with advanced methodology for testing and experimenting with the sets I have built. Each section is useful and understandable to the hobbyist with moderate to good experience. The handbook will help the beginner to quickly get up to speed and allow the experienced builder to find endless new ideas. This is not a book of Hookups or circuit designs, that is covered in my Catalog of Crystal Hookups.

All of the material in this handbook is copyright for which I have not sought permission. Therefore this is not presented for publication or copy. It is only my personal resource. I encourage anyone finding this copy to pursue ON THE WEB the web pages identified within. I include the name of the author and web address of each section. I wish to sincerely thank every author presented for their excellent pages and ask forgiveness for my editing into this handbook.

Dielectric losses in coils.

When a coil is wounded on a coilformer, there will be dielectric losses in the former. Also in the insulation of the wires there will be dielectric losses, especially when windings are touching each other.

For the coilformer it is important to use a material with low DF value, and to use as few as possible of this material between the windings so the capacitance and losses are kept to a minimum.

Other dielectric losses.

Also in the wires in the receiver dielectric losses can occur. For instance if a wire carrying radio frequencies is placed very close to a other conductor. The two conductors form a capacitor, with the wire insulation as insulator, in this insulation losses can occur.

We can reduce these losses by placing the wire at some distance of the other conductor (some cm. or more).

If we connect this capacitor to a coil, then we have a LC circuit. If the coil has no loss, the maximum Q of the LC circuit will be:

Q= Zc / Rs = Zc / (Zc . DF) = **1 / DF**

So, if we use a capacitor with nylon insulation, the Q of the LC circuit will have a maximum value of: Q= 1 / 0.026 = 38. This is a very low value.

So, a LC circuit with airspaced tunercapacitor has a infinite Q??? No, because there are more losses, like the resistance of the coilwire, the resistance of the capacitor plates, the dielectric losses in the coil, etc.

It is also not possible to use a tunercapacitor with only air insulation. The rotor (turnable part) and stator (non turnable part) must also be connected to each other by insulation material. If for instance 4/5th of the capacitance is caused by air insulation, and 1/5th by nylon insulation blocks, then the Q will increase by a factor 5 compared to a full nylon insulation. So the Q can then be 5x38=190.

The higher the frequency of the circuit, the higher the percentage of capacitance caused by the insulationblocks, and the lower the Q. Instead of nylon it is better to use a insulator with a lower DF value, and preferable also a low εr value.

For a high Q the following is also important:

Use the insulation material only on places where the distance between rotor and stator is high, this helps to reduce the capacitance and losses caused by the insulator.

Don't use more insulation material then necessary.

Polyethylene (PE)	2.26	<0.0002
Polypropylene (PP)	2 .25	<0.0005
Polystyrene (PS)	2.56	<0.00007
Polytetrafluoroethene (PTFE, Teflon)	2.1	<0.0002
Polyvinyl chloride (PVC)	2.88	0.016

A capacitor wil have at certain frequency a impedance of:

Zc=1/(2.pi.f.C)

Zc= impedance of the capacitor (Ohm)

pi=3,14

f= frequency (Hertz)

C= capacitance of the capacitor (farad).

Because of the losses caused by the insulator, it looks like there is a resistor connected in series with the capacitor. This is the series resistance (Rs) of the capacitor.

If the insulation of the capacitor has a certain DF value, the series resistance wil have a value of:

Rs=Zc . DF

In the ideal case a capacitor has no loss, if we send a AC current through the capacitor there is no loss of energy. In practice there will always be losses, if we send a current through the capacitor a part of the energy will get lost by heating up the capacitor.

These losses are caused by:

a- The resistance of the conductors (plates), these losses are left out of consideration here.

b- The dielectric losses in the insulation. One insulator gives more dielectric losses then the other, this is indicated by the dissipation factor DF. The dissipation factor "DF" is sometimes also called: "tangens delta".

The lower the value of DF, the better the quality of the insulator.

In the following table some values of εr and DF for different insulation materials.

Material	Dielectric constant (εr) at 1 MHz.	Dissipation factor (DF) at 1 Mhz.

CRYSTAL SET DESIGN 102

Copywrite 1997, 1998 - Alan R. Klase - All rights reserved.
http://www.skywaves.ar88.net/xtalset102/xtalset102.htm

Introduction:

Welcome to Crystal Set Design 102. It is assumed that you've already completed the 101 level course elsewhere, and know, at least, something about electronics in general and crystal radios in particular. If not, hit the books. The stuff in your public library will get you started. The early chapters of the "Radio Amateurs Handbook" are especially concise and approachable.

I've been a little disappointed at the lack of meaningful crystal set technical information on the web and in current literature. This is my attempt to at least partially remedy this situation. This work is the result of about ten years part-time investigation of crystal radios from an engineering perspective. Serious development of passive receivers pretty much came to an end with the introduction of reliable vacuum tubes around 1920. A lot of crystal sets, both commercial and home brew, have been designed in the interim, but most are mediocre performers. So the mission turned out to be one of rediscovering the the secrets of the age when spark was king.

Getting Started:

My approach is to build crystal radios out of quality vintage radio parts. They are available in great profusion at amateur radio "hamfests" and antique-radio meets (and in my garage). If you don't have access to these sources, I'd suggest you start at Radio Shack: Buy their Crystal AM Radio Kit, 28-177, for $6.99. This is actually not a bad crystal set, and it contains a coil, a variable capacitor, a germanium diode, and, most importantly, a reasonably sensitive high-impedance ear phone. You're also going to need an antenna. This generally means wire up in the air. The attic may be the next logical alternative. Apartment dwellers may be in trouble unless you're near an AM radio station, or can arrange a "stealth" antenna of some sort.. Again, if you don't (yet) have a junk box, get Radio Shack's Outdoor Antenna Kit, 278-758, for ten bucks. Wire has always been expensive, and hard to find retail, so keep your eyes open for bargains. Another RS item, that's almost indispensable, is a set of mini-alligator jumper cables, 278-1156, 10 for $3.99. These are how you make temporary "breadboard" hookups while experimenting with new circuits. You'll also want basic electronic hand tools and a soldering iron.

Circuits:

The simplest radio you can build is just a diode detector and a headset. With a reasonable antenna and ground you will hear the strongest stations, albeit all a once. This is not much of a

---

INSULATION MATERIALS

Dick Kleijer crystal-radio.eu
http://www.crystal-radio.eu/enisolators.htm

For insulation materials used in crystal receivers the following electrical properties are important: insulation resistance, dielectric constant and dissipation factor.

Insulation resistance.

This is the resistance between two conductors having a insulation material in between. In most cases the insulation resistance is high enough for use in crystal receivers.

Dielectric constant.

Two conductors with insulation in between form a capacitor. If the conductors have the shape of parallel plates then we can calculate the capacitance as follows:

$$C=0.0885\ \varepsilon r\ A / d$$

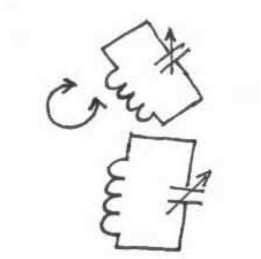
C= capacitance in pF (picofarad)

εr=dielectric constant of the insulator (ε = the Greek letter Epsilon)

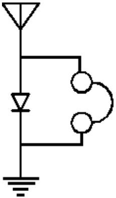
A= area of the plates in square cm. d= thickness of the insulation in cm

The value of εr indicates the increase of capacitance compared to air insulation.

Dissipation factor.



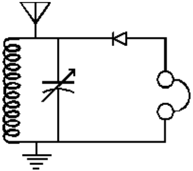
Capacitive coupling
Coupling is adjusted by a variable capacitor with a very low value (e.g. 1 pF). There must be no coupling via the magnetic field, so the coils must be placed at a right angle. Capacitive coupling is also useable when magnetic coupling is difficult, for instance when using ringcore or potcore coils.



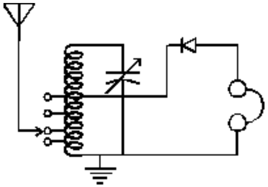
radio. but it will give you some indication that you have enough signal strength to continue experimenting.

The primary problem with the above set is that it offers no selectivity. We'll solve this problem by building a tunable filter. This will generally consist of a coil and a capacitor forming a tuned circuit. Either the capacitor or inductor, or both need to be variable so circuit can be tuned to different stations. The classic values are 250 uH and 365 pF to tune the broadcast band. This is the basic crystal set schematic you'll find almost everywhere. It works better than just a diode, but has some serious short comings that are easily remedied.

The Importance of Impedance Matching:



In a crystal set, all the audio power that arrives at your ear drum came from the distant transmitter. If the transmitter is hundreds of miles away, the amount of power captured by even a good antenna is reckoned in nanowatts . At each point in the set we must strive to transfer at least a reasonable percentage of the available power to the next stage. Perfect impedance matching is not necessary, don't fret over a 2 to 1 mismatch, but let's eliminate as many of the 10 to 1 and 100 to 1 mismatches as we can.



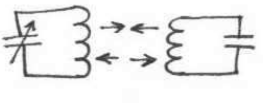
Single-Tuned Sets

In the case of the simple set in the last example, lets do two things: Tap the antenna input "down" on the coil. The impedances of the antenna and tuned circuit will vary with frequency, so it's a good idea to provide multiple taps and a selector switch or movable jumper. As a starting point tap the coil at about 5%, 10%, 20%, and 50% of the total number of turns from the ground end of the coil. Secondly, connect the detector to the 50% tap. This does two things, both of them beneficial: It provides a better match to the detector when it's connected to the usual sort of crystal set headphone that has an impedance of about 10K ohms, resulting in a louder signal. It's also reduces the loading on the tuned circuit, increasing it's Q and consequently it's selectivity.

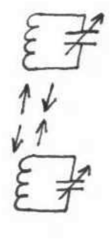
These improvements result in a better than average crystal radio. With 50-75 feet of wire up in the air, you should hear daytime 50KW stations out to 40-50 miles, and night-time skywave stations will come in form hundreds of miles away. This is essentially the circuit I arrived at for my Cub Scouts a few years back. (See *The Den Two Crystal Radio* in *Crystal*

There are several methods for adjusting coupling. The methods shown below are mostly used in crystal receivers.

The coils are side by side
Coupling is adjusted by varying the distance between the coils.



Coils behind each other.
Coupling is adjusted by varying the distance between the coils.

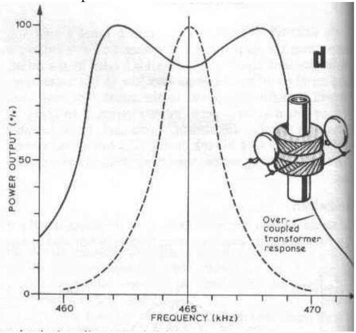


One coil is turnable.
Coupling can be adjusted by varying the angle between the coils. With both coils in the same direction, the coupling is maximal. Turning the angle towards 90 degrees, the coupling will decrease. With a angle of 90 degree, there is no coupling at all.

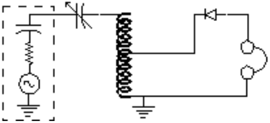
Overcoupling
The coupling is too high because the distance between the coils is too small.

The bandwidth is too high.

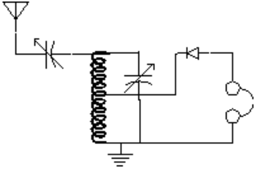
The curve shows two peaks, the higher the coupling , the higher the distance between the peaks, and the deeper the dip between the peaks.



Set Projects published by The Xtal Set Society) You'll also notice it's almost exactly the same circuit used in the Radio Shack set

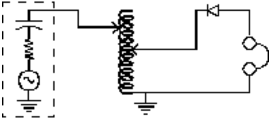


Another effective way to match the antenna to the tuned circuit is to use a variable capacitor as shown in the drawing. A cap in the 300-500 pF range is appropriate. Tune in a station then change the coupling and retune and see if there's an improvement. Some sets have the coupling capacitor in the ground lead instead of the antenna lead. Electrically it's the same thing, but sometimes it's more convenient for mounting and grounding and eliminating hand capacitance effects.



With the previous circuit, connected to a good sized antenna, you'll find you can set the tuning capacitor to it's minimum value, or even remove it completely and still get good performance. To understand how this "series tuned" receiver works, I've inserted the equivalent circuit of the antenna in the drawing. Any Macroni antenna less than a quarter wavelength long appears to be a capacitor in series with a small resistor, known as the radiation resistance of the antenna, and an RF voltage source. This is almost always the case as a quarter wavelength, even at the top of the broadcast band, is 187 feet. Our aim is to make as much RF current as possible flow from our antenna. When the series value of the antenna and tuning capacitors and the inductor are tuned to the frequency of interest, the inductive and capacitive reactance's cancel out, leaving only the DC resistance of the inductor. This results in maximum current flow in the tuned circuit, and maximum voltage applied to the detector. A receiver of this sort will usually require a variable inductor to cover the entire broadcast band. In such cases, keeping the detector connected to the optimal point on the coil presents challenges.

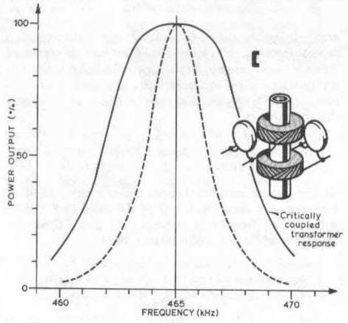
One classic variation on the series tuned receiver, known as the "two-slider tuner", dispenses with the tuning capacitor entirely. Instead a sliding contact on the coil varies the inductance in the antenna circuit. A second slider connects the detector at the best point on the coil. Total inductance should probably be the better part of a millihenry



Critical coupling
There is maximal powertransfer.

The bandwidth is higher than in a single circuit, and also also higher than a undercoupled circuit.

The response curve is flat in the top over a smal part.

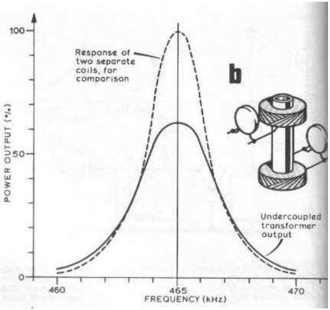


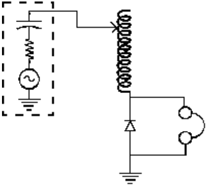
Undercoupling

The coupling between the circuits is too low, because the distance between the coils is too high.

There is no maximum powertransfer from one coil to the other.

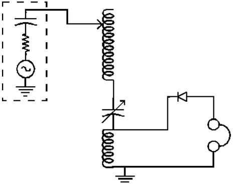
The bandwidth is higher compared to a single circuit.





Yet another, historically common circuit, connects the detector in series with the variable inductor. This is not such a great idea from the standpoint of impedance matching, but it is simple. Series tuned sets all have difficulties with short antennas, because their capacity is low.

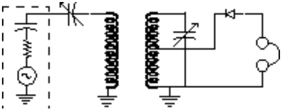
Another way to implement the series tuned set, that improves the match to the detector, is to connect the detector and headset across a second coil in the series circuit. For the broadcast band, this coil has a fixed value of approximately 80 uH. The variable capacitor is optional, especially if the larger inductor is continuously variable.



Single-tuned crystal sets, whether series or parallel tuned, leave a lot to be desired in terms of selectivity. Yes, the nose selectivity can be improved by increasing the Q of the tuned circuit, but the skirt selectivity remains hopelessly broad. The obvious solution is to use more than one tuned circuit. The point of diminishing returns is between 2 and 3 circuits for a crystal set due to cumulative losses and tuning difficulties.

The Two Circuit Receiver

The classic solution is the "two circuit" tuner. The antenna circuit is series tuned by a variable capacitor and an inductor, while the detector circuit is connected to a parallel LC circuit. The amount of mutual inductance, or coupling, between the primary and secondary circuit is generally made variable. This allows light coupling to be used to obtain the sharpest tuning, while increasing the coupling increases sensitivity at the expense of selectivity. This is essentially the same architecture used to great effect in the communication receivers of the wireless era. If you're seeking better performance for your crystal set this increased complexity is well worthwhile.



There are several way to implement variable coupling in the two-circuit set. The navy style "loose couplers" used a secondary coil that telescoped inside the primary. Other possible schemes include variable taps on the low end of the secondary coil, link coupling between the two coils, or the use of a small variable inductance common to both circuits.

COUPLED CIRCUITS

Dick Kleijer crystal-radio.eu
http://www.crystal-radio.eu/enkoppelfactor.htm

In a receiver having two tuned circuits, both circuits must be tuned to the same frequency.
De 2 coils of the tuned circuits must have a certain distance in between, via the magnetic field around the coils, the circuits are coupled to each other. The distance between the coils determines the degree of coupling, the smaller the distance, the higher the coupling.

The -3dB bandwidth of a coupled circuit is higher than with a single tuned circuit.

The suppression of frequencies at some distance from the tuning frequentie is in a coupled circuit better than with a single circuit, this is good for suppressing strong local station.

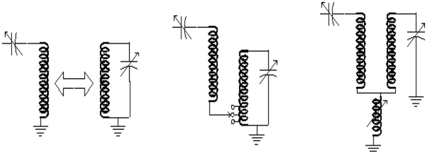
In the pictures below you see the response of the coupled circuit at different degrees of coupling. For comparison the response of a single tuned circuit is shown as a dotted line.

The pictures are taken from a radiohandbook, and are about a coupled filter for 465 kHz, but the theory is usefull for all coupled circuits, so also for crystal receivers with two tuned circuits.

Here we see, that at a constant value of Rp, the Q will decrease with increasing frequency (f). A parallel resistance across the circuit will especially give a reduction of Q at higher frequencies.

The value of Q will both depend on series and parallel resistance, it is possible that a LC circuit gives a increasing Q at increasing frequency (because of series resistance) and than Q will reduce (because of the parallel resistance). In this case we have a peak in Q somewhere in the frequency band.

Often the losses caused by the parallel resistance are the highest, and we only see a reduction of Q at higher frequencies in the medium wave band. Than there is also a peak in Q, but this occurs at a frequency lower than we use.



Variable coupling schemes for two-circuit tuners.

Additional Details

The primary inductance will want to have a maximum value of about 500 uH to reach down to 530 KHz. However, a lesser value in needed to reach the 1600 KHz end of the band. I've been building coils with five or six evenly spaced taps. This lets you tune around for an optimum match to the antenna.

Install a DPDT switch to allow the primary circuit to be operated in a parallel-tuned mode: The input end of the primary capicator is grounded, and the antenna attached to the top of the coil. This allows effective operation with short antennas.

If a non-fixed detector is used in a double-tuned circuit, it's a good idea to include a buzzer to generate a local signal to adjust the detector. The circuit is a low-voltage mechanical buzzer, a battery, a push-button switch, and a one-or-two-turn link to the secondary coil. A low voltage relay with it's normally-closed contact wired in series with the coil is a good substitute for a buzzer.

insulators of the tuning capacitor Dielectric losses in materials placed near the coil or tuning capacitor, look here for more information about this subject. If the capacitor plates are not clean: dielectric losses in the dirt and oxide on the capacitor plates.

Also there can be a leaking resistance in insulators, e.g. by moisture.

All these losses together makes a parallel resistance (Rp) across the LC circuit.

Magnetic losses

This occurs when a magnetic material (iron) is placed near the coil. Non magnetic materials (plastic, wood, aluminium etc.) don't give magnetic losses.

Why is the Q factor not constant for all frequencies?

The series resistance Rs gives a reduction of Q. If we leave other losses out of consideration, the Q will have a value of:

Q= 2.pi.f.L / Rs

If the value of Rs is constant, the value of Q will increase with increasing frequency (f). A series resistance in the circuit will especially give a reduction of Q at lower frequencies.

On the other hand: if we only look at the losses caused by the parallel resistance Rp, the Q will have a value of:

Q=Rp / (2.pi.f.L)

Rs=(2.pi.f.L) / Q

The Q factor of a unloaded LC circuit is determined by the following factors: series resistance in the circuit, parallel resistance across the circuit and magnetic losses.

The series resistance in the LC circuit,

the lower the series resistance the higher the Q. The total series resistance in the circuit (Rs) is the sum of:

The wire resistance of the coil, thicker wire or litzwire with much strands helps to reduce wire resistance.

The resistance of the capacitor plates, silvered plates gives the lowest resistance.
Plates with oxide gives more resistance than clean plates.

Contact resistance between rotor and frame of the variable capacitor, preferable the variable capacitor has a spring connected to rotor and frame, this provides a low resistance. When the contact is made with a slidercontact at the rotor, this must be clean and free of oxide.

The parallel resistance across the LC circuit,

the higher the parallel resistance, the higher the Q.

Parallel resistance across the circuit (Rp) is caused by dielectric losses.

There are: Dielectric losses in the coilformer Dielectric losses in the insulation of the coilwire Dielectric losses in the

CRYSTAL RADIO ANTENNAS

Owen Poole

http://bellsouthpwp2.net/w/w/wuggy/antenna.htm

If there is such a thing as the perfect antenna, then why does every issue of every ham magazine have an antenna article? Fortunately, for the crystal radio nut, most ham antennas are less than optimum for general listening use, and require special care and feeding due to the need to have the transmitter and antenna somehow matched to near perfection and for the antenna and its associated parts robust enough to handle power without arcing and sparking while also keeping the transmitted signal out of the shack and also out of the neighbor's tv set.

Crystal radio antennas have some special requirements:

a. large frequency range
b. large signal gathering capability
c. efficient in getting and then transferring the received signal to the set.

Your basic problem is normally just getting enough wire in the air to have a resonant circuit. For 99 percent of us, the answer is: you can't. Even the shortest resonant antenna for the top of the AM broadcast band, a quarter wavelength *Marconi* antenna, would have to be about 137 feet long; the bottom of band calls for about 425 feet. Unless you are one of the fortunate few to be able to erect a bona fide antenna farm everything you do from this point on will be a compromise of one sort of another. This means you have to start thinking about your antenna system rather than just what you hang up outside the house.

First, the antenna itself: I recommend you use stranded copper wire, at least 20 gage. Try to get at least 50 feet of it "out the window" and up in the air as high and as far from the house as possible. My experience is that anything shorter gets real hard to tune, and gives away a whole bunch of signal to boot. Longer is better, higher is better. Use plastic strips or ceramic separators or whatever you can get to ensure the antenna wire is not touching anything that could be grounded, including the tree you may be using for a support. I usually just use stranded wire with a tough plastic coating, wrapping it over tree limbs as I go, and connect it at the far end with heavy nylon fishing line. **Do not go over or under power lines.** If you are coming in through the bottom of a window, as many of us do, be sure to use insulated wire for the final lead in. If you have to put it inside, such as up in the attic, make sure you are not hanging it under a metal roof or ridge vent, otherwise it could very well shield your wire from the signals you are trying to get. High straight antennas are probably best, but do the best you can, and don't be afraid to bend it in order to get more wire out there. Contrary to popular wisdom, you can tune a bent antenna. If you like to try out different stuff, put an alligator clip on the end in the shack to make quick connections to your latest xtal wonder rig. If you replace your antenna, or otherwise have room, a second antenna can come in handy, if for nothing more than comparison purposes. My second antenna consists of 50 feet of wire out the window, up to the roof, and over to a tree. This is about what I expect my students to get up, and I always use it for testing kid radios. If your main antenna is mostly long and horizontal, a shorter, and more vertical antenna might give some pleasant results,

The table below gives the value of impedance and voltage on the tap's of the coil. Also the current is given which can be given at the tap, the current will increase at a lower tap.

Tap	Voltage on tap	current	impedantie
100 %	100%	100%	100%.Rp
90%	90%	111%	81%.Rp
80%	80%	125%	64%.Rp
70%	70%	142%	49%.Rp
60%	60%	166%	36%.Rp
50%	50%	200%	25%.Rp

The used diode must also have about the same resistance as the impedance at the tap.

Because of the lower voltage at the tap's the diode efficiency will decrease however, and this will reduce the sensitivity of the receiver. The best option is the diode at the top of the coil, and the use of a load impedance with a high enough value.

Series resonance

In a series connected LC circuit, the impedance will be low at resonance. If there are no losses in coil and capacitor, the impedance will be zero Ohm at resonance. But here are also always losses, in serie resonance we keep a certain resistance Rs. The higher the Q, the lower the series resistance Rs.

The Q of a LC circuit will decrease when we connect a antenna or detector to it, this is because the antenna or detector gives extra parallel resistance to the circuit. By doing this the selectivity of the circuit will reduce.

Parallelresonance

In a parallel LC circuit, the impedance will be high in resonance.

If the coil and capacitor has no losses, the impedance would even be infinite at resonance. In practice this is not possible,there will always be losses, for instance in the resistance of the coilwire.

So, the impedance is not infinite, but has a certain value, it looks like there is a resistor connected parallel to the LC circuit, this we call the parallelresistance of the circuit "Rp".

Rp=2.pi.f.L.Q

Parallelcircuit with taps on the coil

As discribed above the parallel LC circuit has a certain parallelresistance.

For maximum sensitivity in a receiver, the load impedance (speaker or audiotransformer) must have about the same value. If we only have a speaker or transformer with a lower impedance, then we can connect the detector diode at a tap on the coil, instead of the top of the coil. The circuit will then not be loaded too much, and the Q and selectivity will not drop.

particularly with distant stations and higher frequencies. Since you will probably be using what is considered a random wire antenna, connected at one end to the set, it may be of some value to know that the horizontal part of the antenna "points" in the direction of best reception off the free end.

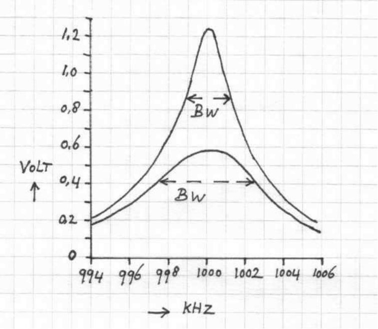
Next, get a good ground. This is the other half of your antenna, and a good earth ground is essential. By earth ground I mean a good electrical connection to the earth. (I once had a student who tried just laying the ground wire on the ground - didn't work) I know of several hams who invest more time, effort and money in their ground than any other part of their antenna system. Mine is currently a tight connection to a close by cold water pipe. If you have plastic pipes, this doesn't work. I have also used pipes hammered into the ground, the ground rod the telephone company provides where their service comes into the house, and even the screw holding on the cover of electrical plug cover plates in a pinch (this is usually electrical ground, and may even lead electrically to the earth somewhere - works better for some locations than others). I haven't resorted to burying assorted lengths of wire in the ground yet, but many dedicated types do. If you are located in the desert or on a granite mountain, and good earth grounds are hard to come by, you need to read up on dipole antennas, ground radial systems and counterpoises; good luck. If you can not make a short connection to a good ground, and your ground lead is long enough to act as an antenna itself, you might want to try this trick: use a piece of coaxial cable between the set and the ground connection, using the inner core for the connection; connect the shield to the core at both ends with a capacitor, say, about 0.01 uF or so, to shield the ground lead from rf. I haven't tried this myself, but it makes sense, I think.

Whatever you have done up to this point, your antenna is (1) too long or too short (usually the latter), (2) is not resonant at the frequencies of interest, and (3) will not efficiently transfer whatever signals you get to your set. Guaranteed. Despite all these deficiencies, it will probably work pretty well, at least on the stronger stations. If you are happy at this point, declare victory and quit. If, however, you have a free hand left with which to flog yourself while you tune with the other, or really want to go after them, read on.

The first quick fix you can make is to effectively add additional length to your antenna by putting a large coil of wire between the antenna and the set. Wind 50 to 100 feet of 20 to 24 gage wire around a core between 2 and 5 inches in diameter, and tap it about every 10 turns or so. Attach one end of this coil to the antenna. Use an alligator clip to connect the xtal set to various taps until you get the loudest signal. While this doesn't add much to the antenna in the way of length, it can make the antenna closer to resonance with the frequency you are trying to dig out.

Quick fix number two, which can be done after or in lieu of number one, is to add some capacitance between the antenna and the set. This seems to work best if your antenna is too long for the frequency of interest. Radio Shack uses this technique in some of their Bunch-in-One electronic project kits, using a fixed 10 pF capacitor for a short antenna and a 100 pF capacitor for long antennas. Short refers to antennas 50 feet or less in length. I prefer to use a variable capacitor if I go this route. Putting the capacitor in series with the antenna this way lowers the inherent capacitance of the antenna. One of the more popular designs a number of years back put the

---



Curve of frequency respons for two tuned circuits.

At the upper curve, the bandwidth is 2.4 kHz.

The Q is 1000 / 2.4 = 416

In the lower curve the bandwidth is 5 kHz.

And here the Q is 1000 / 5 = 200.

The Q of a circuit can vary from less then 100 for coils made with massive wire, up to 400 or more for coils made with litzwire.

Bandwidth:

At resonance frequency the impedance of a parallel LC circuit will reach it's highest value, the voltage over the circuit will then also reach it's highest value.

Above and below the resonance frequency the voltage will decrease.

There are two frequency's where the voltage is 0.707 times the voltage at f.res.

One frequency is just below f.res, this is frequency fl.

And one frequency ia above f.res, this is frequency fh.

The voltage reduction to a factor 0.707 is a reduction of 3 Db

The current is there also reduced to 0.707, and so the power in the circuit is halve the power of f.res. (0.707 x 0.707 = 0.5).

The bandwidth of the tuned circuit is: **BW =fh - fl**

Circuit Q:

The Q of the circuit is:: **Q=f.res / BW**

The higher the Q, the smaller the bandwidth, which is better for separating adjacent stations. And also, the higher the Q, the higher the voltage which the received station gives over the circuit, so a more sensitive receiver.

variable capacitor in between the xtal set and the ground connection. If it is the same size as the main tuning capacitor in the rig, you can even gang them and make tuning a bit less tiresome, with little or no adverse effect on results. This actually works very well. If you are using a set that has the detector or the antenna attached directly to the top of the tank circuit, and don't want to make taps in the tank coil for better impedance matching, this fix might be(I should say is) essential, and is certainly worth trying. The problem with connecting the antenna to the top of the tank circuit coil is complex, to say the least. I observed that the first effect is to lower the resonant frequency of the tank circuit drastically, even with a very short (a few feet) antenna. If you're going to try to get away with this, and don't have a variable capacitor to spare, you can make a gimmick capacitor by twisting a piece of wire connected to the set around the bitter end of the antenna. I did it another way, using some 18 gage twin lead wire; turned out that the capacitance of the twin lead was about 1.2 pF per inch, and the circuit resonance from the antenna was not affected if you used enough twin lead (one side connected to the set, the other to the antenna) to give you about 1 pF per foot of antenna.

Quick fix number three, which is an excellent idea even if you don't do the first two, is to connect the antenna to a tap on the tuning coil. This gives a better match between the impedance of the antenna and the tuned circuit of the rig. Techtronics does this with their nice little crystal set, providing two places to connect the antenna (really three, but they don't mention the third tap, for some reason. It is between the other two.) Probably the absolute worst place, in my opinion, to have the antenna connected is at the top of the set tuning coil along with the connection to the detector, yet that is what several web page offerings would have you do. The tap you use will have to be determined experimentally, but I find that low on the coil close to ground helps.

Quick fix number four, which I recommend with fix number one: Use an antenna coupling coil . Wind the coupling coil on approximately the same diameter core as the main tuning coil, using about one turn for every six in the main tuning coil, and then put it in line (on the same axis) with the main tuning coil, with the ability to move them apart. You will get better selectivity, and can sharpen it up a bit more by moving the two coils apart - what the trade calls loose coupling. Oh yeah, the antenna and ground are connected only to the coupling coil, although you might try connecting the ground to the set as well. The "one for six" rule is just a rule of thumb. If you don't mind experimenting a bit, pick the number of turns on the coupling coil that gives you the best coverage across the band, particularly if you are going to use your set without a tuner. It will still be a compromise, and the best number of turns will depend on the length of your antenna and your location, but will give better results. Of course, you can dispense with the coupling coil if you are inductively coupling the antenna coil directly to the set's tank coil as in the basic tuner below.

If you have tried one or more of the tricks above, and are happy, fine. If not, I don't blame you, so it is time to get serious about tuning the antenna and coupling it to the set for optimum sensitivity and selectivity. In other words, it is time to talk antenna tuning and coupling methods, subtitled "how I went from 5 to 50 stations , and then to 98, heard on my xtal set".

TUNED LC CIRCUITS.

Dick Kleijer crystal-radio.eu
http://www.crystal-radio.eu/enlckring.htm

Frequency:

A tuned circuit made of a coil L (unit: Henry) and a capacitor C (unit: Farad) has the following resonance frequency:

f.res = 1/(2.pi.root (L.C))

Example: a coil of 0.2 mH (0.0002 Henry) is connected to a 500 pF tuner capacitor (0.000,000,000,500 Farad).

The lowest frequency we can tune to is 503 kHz.

If we turn the value of the tuner capacitor to a value of 48.8 pF, the resonance frequency will be 1611 kHz.

Here in Europe 1611 kHz is the highest frequency on medium wave.

So, with this LC circuit we can tune over the entire MW band.

In practice both coil and detectordiode will have a certain capacitance, so we must set the tuner capacitor to a lower value for tuning at 1611 kHz.

If the coil has too much capacity it is possible that we can't reach the highest frequency.

In this case we can add some space between the turns of the coil, this will reduce capacity.

$$R_{shunt} = 2 * \pi * 1\text{ MHz} * \text{loaded } Q * L \qquad \text{Eq. 8}$$

As an example, if we have a 240 uH coil and we want the loaded Q to be 20 at 1 MHz then the total shunt load should be 30,000 ohms. Assuming coil losses are small this means that the detector impedance should be 60,000 ohms and that the antenna impedance should be transformed (via a tap near the ground end of the coil) up to 60,000 ohms. This particular scenario is a practical one that can be built.

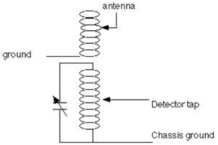
Concluding remarks

Although it is discussed in other chapters it should be mentioned here that we generally want to make the detector impedance as high as possible in order that we can use the highest inductance practical. This results in the maximum signal voltage applied to the detector thus lowering the losses in the detector circuit.

A significant factor to be aware of is stray capacitance across the inductor. This capacitance results from the natural physics of the winding (conductors separated by insulation). This stray capacitance is typically in the 10 to 50 pF range depending on how the inductor is wound and is in shunt with the tuning capacitance. The effect is to limit the upper frequency that the inductor can be tuned too. The effect is worse in large value inductors and that typically limits the maximum practical inductance to something less than 1 millihenry. There are some advanced winding methods that minimize stray capacitance but those are beyond the scope of this chapter.

A properly employed antenna tuner will do a lot of "heavy lifting" for you. First, it can make your antenna resonant at the frequency of interest, and bring up the signal level at the same time. Second, it will screen out a lot of unwanted stations, including those out of band ghosts. Third, it will transfer the signal efficiently to the main tuning and tank circuit, and do so such that you can vary the selectivity of your set as a bonus. This seems like a set of tall orders, but it isn't nearly as hard as it may seem. I will discuss mostly sets using air core solenoid tuning coils (that is, toilet paper rolls wrapped with a single layer of wire or the like), since that's what I usually use and have the most experience with. Before we start, let me say that an antenna tuner is not just another stage of passband filtering, such as the Miller 595 crystal set used. A key to a passband tuner design is when you see a two or more section variable capacitor, with one section in the gang working with one coil and the other section working with the second coil. Also let me add that an antenna tuner is essential for serious work.

Basic tuner : Wind a coil on a core the same diameter as your xtal set's main tuning coil. You may want to add about 30 to 50% more turns, but it should be at least as many turns as are on the main tuning coil. Put a tap at least every 10 turns (every 5 is better). Put the two coil axes in line, and connect the end of the antenna coil that is closest to the xtal set to ground. Attach the antenna to taps on the antenna coil using an alligator clip until you get the best signal.



No direct connection to the xtal set is needed. You should find that you can separate the two coils by a distance of one coil diameter or more and get a good signal; in fact, moving them closer together may even make things worse. The closer the antenna is tapped to ground on the coil, the higher the frequency. You can leave the unused antenna coil turns "dangling", as it were, or attach the antenna to the other end and short the unused turns with the tap - both ways are acceptable. You should be able to notice a difference in signal strength of a station by moving just one or two taps along the coil. If you find that you never need to use more than half the coil for the best signal, even at the bottom of the AM band, don't worry; you may need them later. In this setup, you are essentially making the antenna appear the correct length, so you are in effect adding length to compensate for the short antenna. If you can't inductively couple the tuner to the set's tuning coil, you can attach your earth grond to the chassis ground of the set, and attach the ground end of the antenna coil to a suitable tap on the set's tank coil.

The Teenie Tuner: This is a variant of the basic tuner, using a coil wrapped around a ferrite core. Here's how to make one: Get a ferrite core of some sort, either a rod or a bar. Wrap some typing paper over it and glue the paper into a sleeve - put a spacer between the paper sleeve and the core while winding the coil so that the core will slide easily in and out of the coil after it is wound. Over the paper sleeve, wind a coil of some 50 to 90 turns of magnet wire in a single layer; no taps needed. Glue or tape the coil onto the sleeve. Now, mount the sleeve only on a support, such as a scrap of wood, or in line with the set's coil. Connect one end of the tuner coil to the antenna, the other to ground, and vary the tuning by sliding the ferrite rod in and out of the coil. You should get a range of

be used. The details would be a chapter in of itself but I can tell you that the practical absolute minimum inductance that is useful for a resonator in the AM broadcast band is around 40 microhenries as it is a challenge to obtain a high Qu for inductances less than this in that frequency range. Thus, only the last column of Table 2 is useful.

Determination of maximum practical inductance: This calculation is done the same way as before except that the lowest value of loaded Q is used. That results in a higher inductance. Table 3 is a summary calculation. Again, the top two rows are for reference only.

Table 2: Maximum inductance in Henries

Conclusions:

The conclusions from studying Tables 2 and 3 are that low values of inductance are needed for low impedance circuits and that high values of inductance are needed for high impedance circuits. Typical values of inductance used for the resonant circuit in crystal radios ranges from around 100 microhenries up to around 700 microhenries with more common values in the 200 to 400 microhenry range.

We can work Equation 7 backwards to determine a good value for the net shunt resistance across the coil at 1 MHz as follows.

two across the coil as Rsignal. It was discussed previously that losses in the inductor can be represented by an effective resistance across the entire coil. We will refer to this loss resistance across the coil as Rloss. The parallel combination of Rsignal and Rloss is the net resistance across a lossless inductor. We will refer to this net resistance as Rshunt. From Equation 5 we can write

XL = Rshunt / loaded Q Eq. 6

Thus, using a frequency of 1 MHz

Lmin = XL / (2 * π * 1 MHz)= Rshunt / (2 * π * 1 MHz * loaded Q) Eq. 7

The detector impedance is typically in the 2,000 to 50,000 ohm range. With antenna matching the net resistance, Rsignal, will be half this range as discussed above. Table 2 shows a summary calculation for the minimum value of inductance to use to achieve a loaded Q of 100 for various loads either directly or transformed across the coil. The Q of 1,000,000 row represents essentially infinite Q and the Q of 1,000 is not normally attainable and are shown for reference only.

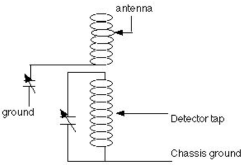
Table 2: Minimum Inductance in Henries

All of the inductances in Table 2 are small –some very small. But our target was the absolute minimum inductance that could

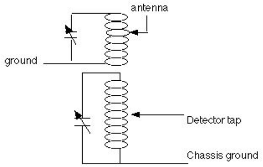
inductance of about 10:1 this way, effectively lengthening your antenna as he rod is pushed further into the coil. As with the basic tuner, you can set the tuning coil alongside the main coil, in line with it, or connect it's ground end to the antenna tap of the set. Just for grins, affix the teenie tuner to the back of your am superhet and see the improvement in your reception.

Series tuner : Here we add a variable capacitor, the same size as the one in your xtal set, in series with the antenna coil used in the basic tuner. Traditionally, you put it between the end of the antenna coil and the ground connection. Now you have two tuner adjustments to make (not counting distance of the antenna coil from the main tuning coil). For the first time, I recommend you get the set tuned to a moderately strong station, then put the tuner capacitor in the mid position, and then find a tap which allows you to hear the station. Then you can use the capacitor to bring in the station more sharply. You will probably find you need to use more turns of the coil than you did with the basic tuner, since the capacitor "shortens" the antenna. Ultimate signal strength may not show much improvement, but it should help selectivity. This setup is a favorite of the "pros". As before, the antenna and main tuning coils are in line. You should have to make fewer tap changes with a series tuner compared to the



basic tuner, since the capacitor does some of the tuning for you.

Parallel tuner : Use the same coil and capacitor as with the series tuner, except this time the capacitor is connected to both ends of the coil. One end of the coil, the one closest to the set, is connected to ground, and the antenna is connected to the coil tap that gives the best signal; incidentally, I have seen a few circuits where the antenna just connects to the other end of the coil from the ground - I don't recommend this, even though it works fairly well, sometimes, maybe, I think. Adjust the capacitor as needed to peak the signal. This setup is often used when the antenna is "very" short.



My recommendation to add turns to the antenna coil will sometimes let you use series tuning across the whole band. If your two coils are the same length, I think you will find that the series arrangement works best at the high end of the band, and the parallel arrangement is needed at the bottom; the longer your antenna, the lower in frequency you can use a series tuner. As with the series tuner, a parallel tuner gives you more selectivity than does the basic tuner.

Although there are an infinite number of combinations of inductance and capacitance that will resonate at a desired frequency there is only a limited range of practical values that can be used. An excellent question to ask is if there is an optimum inductance. If there is then that is what we will use. There is not a specific answer to that question other than there is an identifiable range of inductance that provides the best overall results. We will determine the extremes starting with the minimum practical value that will result in the highest allowable loaded Q followed by calculating the maximum practical value that will result in the lowest acceptable loaded Q. Any practical value of inductance between these two extremes can be used.

Determination of minimum practical inductance: As discussed previously, the highest loaded Q of resonance that is practical to use is such that the 3 dB bandwidth is about 10 kHz. This permits the full double sideband width to be detected. In extreme cases where we are willing to forfeit some audio fidelity to achieve better selectivity the bandwidth can be reduced to about 6 kHz –but we are not going to consider that case here. At 1 MHz (the rough center of the AM broadcast band), a 10 kHz bandwidth occurs with a loaded Q of 100. The antenna and detector circuits may be operating from taps on the inductor for the purpose of impedance matching (the method to design the taps is discussed in another chapter). The impedance at each tap can be transformed to an equivalent impedance across the entire coil. We will assume that the antenna circuit and detector circuit are impedance matched via this tapping process (this provides the much needed maximum power transfer from the antenna to the detector). Thus, for the impedance matched condition the antenna and detector impedance will transform to the identical impedance across the inductor. We will refer to the net parallel impedance of these than about 50 so that the bandwidth is not too narrow. An excessively narrow bandwidth makes tuning very sharp and also distorts the audio. The bandwidth needs to be at least 10 kHz with 20 to 50 kHz being common. The following table illustrates the maximum, typical, and minimum loaded Q values to use across the AM broadcast band. Keep in mind that the unloaded Q of resonance should be significantly higher – preferably in the hundreds. The maximum Q value is for the minimum bandwidth of 10 kHz. The typical Q is a good value to try to achieve although realistically it is likely to be lower. The minimum Q has a fairly wide bandwidth and will not be able to separate stations well.

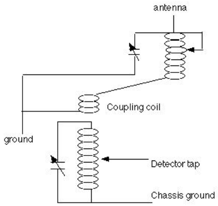
Frequency	QLmax	QLtyp	QLmin
0.5 MHz	50	25	10
1.0 MHz	100	50	20
1.7 MHz	170	85	34

Table 1: Practical ranges for Q of resonance in the AM broadcast band

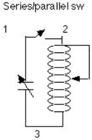
The resonator has an effective resistance across it that represents coil losses. This resistance will be referred to as RQ. Ideally, RQ is infinity (i.e. no losses) but realistic values are typically in the many tens to hundreds of thousands of ohms. There are two loads on the resonator –one is effective source resistance, RS, of the matching network to the antenna and the other is the effective load resistance, RL, of the diode detector and audio transducer. For maximum power transfer from the antenna to the audio transducer the source and load resistances should be equal.

How to determine the required inductance

A broadband tuner : This is not a classic design, to my knowledge, and I stumbled on it by accident, but it does a lot of heavy lifting, and helped me well over the single digits in stations heard. I thought I was copying faithfully a design out of an ARRL handbook for dealing with random length antennas, but ended up with something a bit different, and won't try to analyze how it works, but here it is: Don't sweat the coil/capacitor specs; what you have in the series or parallel tuner will work fine. However, the connections shown going to receiver antenna and ground are actually connected to that coupling coil I mentioned up in quick fix number four. The tuner's orientation with respect to the set is not a factor, since the signal is transferred via the coupling coil. It will generally be closer to the main tuning coil than described in the three tuners above. I like this tuner arrangement for casual listening, as I don't have to play with it much over the band. Find the settings that work best for you. It is a particularly good setup to use when you are finding out about a new xtal set, and don't want to have to mess with the tuner every hundred kHz or so, as you do with a more selective tuner, or don't want to "tailor" a tuner just for the new rig. This setup works well when you can't inductively couple the antenna tuner to the set. It also works without the coupling coil by connecting the end of the antenna coil to a low tap on the main tuning coil of the set.



All of the above tuning methods can be accomplished using a simple coil and capacitor arrangement, which I made up according to the schematic below:



Points 1, 2 and 3 are connecting points for antenna/ground as needed. Antenna can be connected directly to coil taps if desired.

A selective tuner: Richard O'Neill used this tuner effectively in the 1999 DX contest (and everybody used it in the 2000 contest), and it is perhaps best known in connection with the Tuggle Circuit, which is described in detail in a couple of fine (and inexpensive) publications of the The National Radio Club / DX Audio Service. Essentially, it is the same as a parallel tuner, except, you use a ganged capacitor, such as a dual 365 pF capacitor (some are still around), or even a "superhet" variable capacitor with an antenna and an oscillator section. One section (the larger one for a superhet capacitor) is in parallel with the antenna coil, and the other is between the parallel circuit and ground. I have tried this and it seems to work fine, and is very sharp. As before, try attaching the antenna to taps on the coil for best results; I find attaching it to the top of the coil works fine. Several popular crystal sets have used same double capacitor arrangement. If you don't use ganged capacitors, tuning this baby can be really tricky, since the two (make that three) capacitors interact a lot. When hooking this up to a ganged dual capacitor, the antenna and the top of the antenna coil are hooked to one stator. The bottom of

Q = reactance / Rseries Eq. 6

Inductors and capacitors have internal losses which appear as a resistance load either in series or shunt with the component. Losses in picofarrad capacitors used at broadcast frequencies tend to be very small and thus these capacitors have a high Q (typically many hundreds) or as it is more commonly referred to in capacitors, low dissipation (the reciprocal of Q). Inductors have the dominant loss. This loss is commonly the series resistance of the wire (including skin-effect) but can also include losses in any magnetic medium used in the inductor. For good crystal radios we need inductors to have a Q in the hundreds.

Resonant circuits are not used in isolation. The antenna is coupled to the resonator as well as the diode detector. Both of these represent a resistive load which lowers the Q of resonance. This is referred to as the loaded Q. That may sound bad but it is actually fine. The loads represent power that we are interested in. We prefer that the resonator have low losses or high-Q. That permits the maximum transfer of power from the antenna to the detector.

Since any resistive load such as the antenna radiation resistance or the detector resistance lowers the net Q (i.e. Qloaded) of resonance, it is important to start with a high unloaded Q known as Qu. The Qu of an LC resonant circuit is primarily determined by the Q of the inductor as its losses tend to dominate. Typical values for the inductor Q range from around 50 to over 500. If the tuning capacitor is of very good quality (i.e. air or silver mica insulation, etc.) then its Q will typically be in the 500 to over 2000 range. Although we like for the unloaded Q of the resonator to be as high as practical for low losses, it is desirable for the loaded Q to be no more

The required tuning range, Cmax / Cmin, of a variable capacitor can be determined using Equation 2 as follows

$$\frac{\mathrm{Cmax}}{\mathrm{Cmin}} = \frac{\dfrac{1}{(2 * \pi * \mathrm{Fmin})^2 * L}}{\dfrac{1}{(2 * \pi * \mathrm{Fmax})^2 * L}} = \frac{\mathrm{Fmax}^2}{\mathrm{Fmin}^2} \qquad \text{Eq. 3}$$

For the AM broadcast band Fmax is generally 1.7 MHz and Fmin is 0.54 MHz. Thus, the ratio of Cmax to Cmin should be around 10.

Tuning inductor

The classic ancient method of making a variable inductor was to provide a movable wiper to connect to individual turns of the winding. Modern methods use a movable ferrite rod to vary the inductance. Similarly to the development of Equation 3, the ratio of Lmax to Lmin is the square of the desired frequency ratio and works out to be around 10 for the AM broadcast band.

Discussion of Q

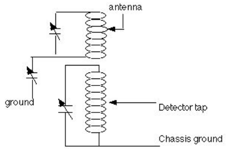
Q can be defined in several ways and each way is compatible with the others as shown below.

Q = resonant frequency / bandwidth3 db Eq. 4

Q = Rshunt / reactance Eq. 5

the coil goes to the rotor (frame), and the ground to the second stator. Note that with decent Q coils, you will experience some hand capacitance effects. I simply used some 9/32 " aluminum tubing on the 1/4 " capacitor shaft, then used about 2 inches of 1/4 " dowel rod as an extension, and put the tuning knob on the dowel; worked fine. Sometimes, when tuning the top of the band (higher frequencies), I can spread the tuner out a bit by making it a series tuner. All I have to do is disconnect the first stator from the top of the coil. Yeah, this means the ground is not attached to the rotor as in a proper series tuner, but it works fine, particularly if you have already done the hand capacitance elimination step.

As long as you have gone this far, why not try connecting the detector to the top of the detector coil instead of to a tap. Works pretty well with a crystal earplug, and cuts out the shortwave intruders. With magnetic phones, using an impedance matching transformer per Ben Tongue's page is rally the thing to do. However folks, with the tuner you already have an additional filtering stage in operation, and can sacrifice a bit of selectivity with the high detector tap; anything to get rig of the intruders in a pinch, particularly in the early evening when they can take over your set.



While I mentioned putting the two coils on the same axis, you can also place them side by side, as Mike Tuggle does with his Lyonodyne #17 (getting 2500 mile contacts), using an antenna tuning coil wound with Litz wire on a ferrite rod; just make sure they are parallel for maximum coupling. You can vary the coupling by either separating them from each other or by rotating one of them from the parallel position, as is done with variocouplers. Minimum coupling occurs for a given distance when the axes of the two coils are perpendicular.

For you people using toroids in your xtal set, I have only to offer what you see in the "quick fixes". My tuners essentially rely on loose coupling to the main coil, and I really haven't played with the other type tuning coils enough. Al Klase uses toroids in his very fine crystal set, and you should look at his page for coupling to that. Also look at his work on XTAL Sets 102 for ideas.

In your quest for sensitivity and selectivity, you may now be ready to try a wave trap, sometimes known as a QRM coil, to get rid of offending, overbearing bandmaster stations. The premise is simple; trap the strong signal and it won't bury the weaker ones. While I can separate two local stations that are 40 kHz apart, with one of them at least 3 dB louder than the other one, I often can't eliminate the louder station entirely, and can often hear it in other parts of the dial except when I am between stations. Then there is the signal from the secret Radio Habana transmitting site, which pokes through at odd times. Crystal radios tend to go with the signal that is the loudest, hanging on until something better comes along. A decent wave trap just might be the answer. . One basic design is around a high resistance coil, 32 gage wire or so, in parallel with a variable capacitor, and a 15 turn link around the coil which connects antenna to set (or wherever you want to

Note that the Q=100 curve has a band-pass of 10 kHz which is about the minimum that can be used to recover the entire double-sideband signal.

Tuning capacitor

Generally, when the capacitor is variable, the inductor is fixed and visa-versa. Mechanical variable capacitors (often 10 –365 pF or similar) were very popular in older times but are more difficult to find in modern times. A modern substitute can be made using one or more rotary switches as will be illustrated later.

The well know equation for the resonant frequency of an inductor and capacitor is

$$F = \frac{1}{2 * \pi * sqrt(L * C)} \qquad \text{Eq. 1}$$

where
F = resonant frequency in Hz
L = inductance in henries
C = capacitance in farads

For a given inductance the required value of capacitance can be determined from

$$C = \frac{1}{(2 * \pi * F)2 * L} \qquad \text{Eq. 2}$$

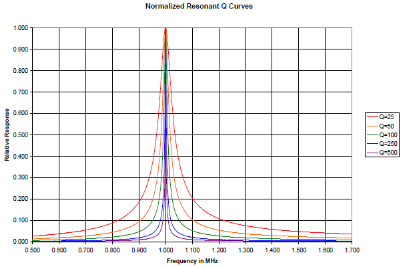


Figure 1: Normalized resonance curves at 1 MHz

Figure 2 shows a zoomed in version of Figure 1.

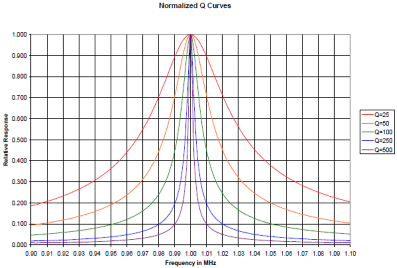

Figure 2: Normalized resonance curves at 1 MHz

try it. The idea is that the resonant LC circuit not only is set into motion by the offending signal but also dissipates it in the high resistance windings of the coil. The link lets the other signals bypass the trap with little loss. Here is a link to a nice short page on wave traps. http://pages.ca.inter.net/~funk/trap.GIF These traps, with no coupling coil, work best for out of band intruders when used as in-line traps in the antenna line, or when inductively coupled to your set's tank circuit. I think the one I use is better for in-line use, and you can find a description, picture, and discussion of it and trapping in general here . I realize that a wave trap might not be considered technically a part of the antenna system, but as long as it is in front of the main tuning circuit, I will consider it so. Wave traps can be used as either rejectors, to block an offending station, or as acceptors, which can be sometimes used to boost a desired station or, more commonly, to add another stage of filtering to increase overall selectivity.

Antennas for the short waves, some notes and preliminary tests (a/o Nov 01):

When you go for the short wave bands, and I think you'll be pleasantly surprised when you do, you will find that even your 50 foot long antenna is more than a quarter wavelength long on even the 49 meter broadcast band. This is a bonus, but also calls for some different ways of holding your head on tuning the antenna to resonance and then coupling it to the detector circuit. If you're like me, you use some sort of coupling coil to the detector tank circuit, and a simple coupling coil will only make the antenna appear longer. My first attempts to couple the antenna to the set and tune it at the same time were somewhat frustrating, especially since I was trying to tune from about 5.8 - 15 MHz. A combination of coils and capacitors that worked on one band did not on another. Then Steve Holden made this timely posting on the Crystal Set Radio Club forum, and I got a better appreciation of the problem:

In the October 1934 edition of Short Wave Craft, Editor Hugo Gernsback writes about Short Wave antennas on page 344. On page 345, fig. 6 shows a schematic of an antenna tuner that is a Coil in series with the antenna, with a parallel Variable Cap (C1); under the Coil is another Varicap (C) that goes to ground.

Gernsback writes, "In figure 6 we have endeavored to strike a happy medium, that is, an antenna that can be tuned and will respond to the SW broadcast bands, 19, 25, 31, 49 meters. The length of the antenna from A to B, that is the flat top and including what leadin may exist, should be 75'. The ground lead should be as short as possible, not over 4-5' long. With C, C1, and L it is possible to tune this antenna to any of the 4 bands mentioned. On some bands it will be a Hertzian and on others it will function as a Marconi. On the 49 meter band a Hz ant. will need to be 80' long. By setting C to a minimum the system becomes, in effect, not grounded. Therefore L and C1 can tune it up to an effective length of 80'. In the 31 meter band this antenna functions as a 3/4 wave Marconi. C should be adjusted to approximately half, and the tuning done with C1. In the 25 meter band,it is also a 3/4 wave marconi, and it is necessary that the effective length be reduced to 60'. This is accomplished by the adjustment of C with C1 set to minimum capacity. In the 19 meter band it is possible to make

RESONANT CIRCUIT

by Kenneth A. Kuhn

http://www.kennethkuhn.com/students/crystal_radios/resonant_circuit.pdf

The resonant circuit plays a very important role in a radio receiver. Its primary purpose is to be a tunable narrow band-pass filter for selecting a desired station while rejecting undesired stations. An important secondary purpose is to be a means for transforming the
low impedance antenna up to the high impedance detector.

A resonant circuit is comprised of an inductor and a capacitor, one or both of which may be variable. Energy flows back and forth between the inductor and capacitor at the resonant frequency. Energy in the inductor is stored in a magnetic field and energy in the capacitor is stored in an electric field. If there were no losses, this cyclic process could continue forever. In reality there is some loss each time the energy moves. This loss is expressed as a resistance. A common term used to account for this loss is Q which is the inverse of the loss. Thus, a high-Q resonance has very low loss and the cyclic process can continue for many cycles. A common example is a bell which continues to ring long after being hit.

Figure 1 shows the frequency response of a resonant circuit at 1 MHz for a range of Q.

voltage across the LC circuit

The voltmeter measures the detected DC voltage

The load resistor is formed by resistor R parallel with the voltmeter with 10 MΩ input resistance

The value of capacitor C is: 100 nF

The RF signal is supplied by a DDS signal generator, the signal is via a coupling coil coupled to the LC circuit.

All measurements are done at a frequency of about 1500 kHz.

At 1500 kHz, the impedance of the unloaded detector unit is: 1.97 MΩ.

There are 4 (combinations of) diodes tested.

HSMS-282K Schottky diode (2 diodes in one case parallel)

HSMS-282K Schottky diode (1 diode)

5082-2835 Schottky diode (2 diodes parallel)

5082-2835 Schottky diode (1 diode)

the antenna function as a 5/quarter wave Marconi. The necessary length here is 75 feet so we can use C for tuning and C1 should be set at minimum." In the next paragraph he talks about coil making, 20 turns DCC (double cotton covered} on a 1" diameter form. He ecommends inductive coupling to the radio. From context I think the caps are standard MW units.

In other words, what Gernsback was saying was that I should use a Tuggle type tuner, but independently tune the two capacitors. Since I was already tuning through some 10 MHz of bandwidth with a 180 degree rotation of the dial, the thought of trying to get three capacitors to tune to the same frequency was somewhat daunting, particularly since my simple sets are typically calibrated by "feel". So, I started playing around a bit more, and finally (I think) came up with a coil/cap combination that gets me back to one knob antenna tuning. I used a coil of about 5 uH in parallel with the 160 pF section of one of the little polyfilm tuning capacitors, attached the antenna to one end of the tank circuit, and the ground to the 60 pF section of the capacitor. I got a dip using a grid dip oscillator across the tuning range of the detector tank circuit, and it seems to work pretty well with both my 50 foot and my 160 foot antennas. Now I am at least back to two handed tuning - hi.

Here is another approach I tried, and it works about as well (if not better), and I don't really know why. I make a tank circuit duplicating the tank in the detector circuit, and then attached just the antenna to the top of it. Darned if it didn't work well, and I was able to separate the two coils by as much as a couple or more coil diameters. Haven't tried it yet, but it might be that you can get the two circuits to track, and use a ganged capacitor. Mike Tuggle gets his best results without a ground, so maybe I'm on to something here. Yeah, someone out there is chuckling as they read this, having known -this all along, but I'm the one with the web site, so I'll take the credit - hi.

Final warning! When you do anything to the antenna system, you can expect it to affect some other aspect of the crystal radio's tuning. When you are ready to start making adjustments, have a comfortable chair, a tall drink, maybe something to make notes with, and the time to be patient. And oh yeah, I didn't even mention the possibility of using different antennas, different grounds, loop antennas, no ground at all.... and did I mention lightning arrestors?

If you noodle around on the web a bit, you will find some excellent antenna articles. I am just trying to get you started. As I said before, every antenna is a compromise - just try to get a setup that works for you, and then you can get back to building and testing your own crystal set creations.

A word or two about small loop antennas, portable antennas and the like: You will find at times references, plans and testimonials in praise of the small loop antennae. If you live near strong stations, they may work for you. Where I live, they are almost useless, and do require a ground. I personally believe that if you are going after the distant stations with a loop you will be very disappointed. These are specialty antennas and have limited value - but where they do work, they get high marks. As an aside, I suspect that if you can't get at least 30 feet of honest antenna out the window, you might

---

EXPERIMENTS WITH A DETECTOR UNIT

Dick Kleijer crystal-radio.eu
http://www.crystal-radio.eu/enantunittest1.htm
On this page measurements are described on my detector unit 1 .

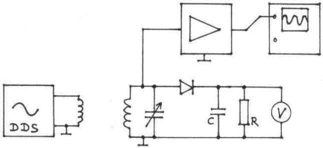
In this detector unit is as diode used the HSMS-282K (2 diodes parallel), and the load resistance by transformer unit 1 is 1.6 MΩ.

For the choice of diode and load resistance I assumed that maximum sensitivity would occur if load resistance and diode resistance were about equal to the impedance of the unloaded LC circuit (this assumption is however not correct).

Via some experiments I will now determine if the sensitivity and selectivity can be improved by the use of another detector diode and/or another load resistor.

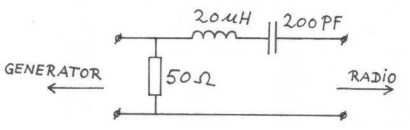
Also frequency shift of the detector circuit is measured as a function of the voltage across the circuit.

Test setup used for the measurements on this page.



The oscilloscope measures via the measuring amplifier the try a large diameter loop antenna instead. If you are new to this business, start at the top with an honest antenna (please try for at least 50 feet out the window), and then, when you start getting experience, and have a set you know works, try what you like. Trying to hook up a first crystal set with a small loop is an invitation to frustration.

Made with a resistor of 50 Ohm, a coil of 20 uH, and a capacitor of 200 pF. The 50 Ohm output resistance of the signal generator is in parallel with the 50 Ohm resistor.



The dummy antenna makes the receiver input is driven with a impedance of 25 Ohm in series with 20 uH in series with 200 pF.. This is about the impedance of a average longwire antenna. With the dummy antenna connected to the generator (but without the receiver connected), the output voltage of the generator is adjusted to 50 mV peak-peak.

Now with various settings of C1, the frequency range of the circuit, the voltage across coil L1, and the Q (across coil L1) are measured.

The measured voltages are Volt peak-peak.

The frequency range can be slightly influenced by the measuring amplifier which was connected across coil L1.

The circuit L1,C2 has a high impedance (e.g. 1 M.Ohm). But the antenna has a low impedance (e.g. 10 Ohm), tuning capacitor C1 forms a impedance match between this high and low impedance.

With a certain value of C1, there wil be maximum power transfer from antenna to the circuit L1,C2. Then there is maximum voltage across the coil L1, and maximum sensitivity of the receiver. At low frequencies we must for instance adjust C1 to 100 pF, and at high frequencies to 20 pF, but these values are depending on the (lenght of) antenna we connect to it. For the circuit Q however, the lower the value of C1, the higher the Q. More information about this, you wil find here.

Coil L1 is wound with litzwire 660x 0.04mm (660/46 AWG), on a polypropylene former. This coil is described here as coil L12, only the outermost winding is removed to reduce inductance a little bit. This reduced the total wirelenght from 15 to 14.5 meters.

The frame of this antenna unit is made of 8mm polyethene sheet.

Tuning capacitor C2 is driven via a 1:5 vernier drive, so we can tune it very accurate. Tuning capacitor C1 has no vernier drive.

Experiments:

During the measurements the antenna unit is connected to the signalgenerator via a dummy antenna.

The dummy antenna.

CRYSTAL RADIO DXing

Steve McDonald

http://members.shaw.ca/ve7sl/crystal.html

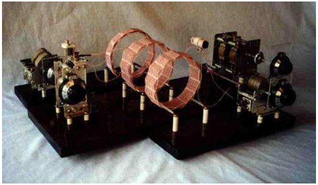
If you are anything like most radio 'nuts', you probably had a crystal set when you were a kid. Thinking back to those good old days, I recall that I could only hear two local stations on my crystal radio. I had always believed that you just couldn't hear very far on a crystal set.....until I ran across this picture!

It was a picture of Al Klase's wonderful "Crystal Radio DX Contest" station! I was amazed to learn that it was even possible to hear 'DX' on a crystal radio and, apparently, there was a large group of very active crystal radio DXers. I was hooked on learning more about this fascinating possibility!

PUSHING THE BOUNDARIES... With some further investigation I turned up the 2001 contest winner, Mike Tuggle in Hawaii. Mike had logged 63 stations and Cuba, all on the AM broadcast band! It turned out that Mike, after years of experimenting, had developed an extremely efficient DX set, which he called the "LYONODYNE 17".

Mike's elegant set is not only a work of art but also 'state of the art', using large diameter basketwound Litz-wire coils and high quality, low loss ceramic tuning capacitors. To be 'legal' in the crystal set community, the radio must be completely "passive", meaning no amplification of any form is allowed. The only power used must come from the antenna, making these DX Contest results even more amazing!

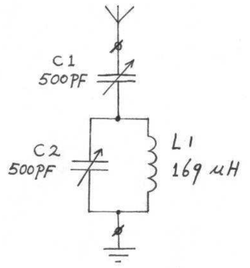
LOCATION! LOCATION!... Crystal-set DXers are up against two problems:



SELECTIVITY versus SENSITIVITY. If you live in a city or near a large city that has several 'blowtorch' AM signals, your main focus will be on separating signals so that the weaker DX can be heard between the blowtorches. On the other hand, if you live in the country, you don't have to worry so much about

EXPERIMENTS WITH AN ANTENNA TUNER UNIT

Dick Kleijer crystal-radio.eu
http://www.crystal-radio.eu/enantunittest1.htm
Here some measurements done with my "antenna unit1".



Schematic of the antenna unit 1.

The antenna unit has a tuned circuit L1, C2.

If we only look at L1 and C2, then the tuning range is 550 - 2184 kHz. But if we also connect the antenna and earth, the frequency of the circuit will decrease, so we can also receive the lowest mediumwave frequency of 530 kHz.

Variable capacitor C1 and the antenna and earth are also a part of the tuned circuit, but the antenna and earth also give reduction of circuit Q.

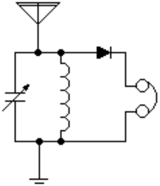
Kevin Smith
09/2011

---

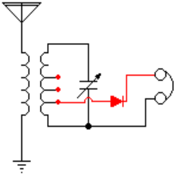
separating strong locals; you can run things 'wide-open' enabling you to log some of the weaker DX signals. Living away from the city certainly makes life simpler for crystal radio DXing but don't despair if you are a city-dweller. One of the DX Contest winners lived in San Jose and still managed to log plenty of DX!

QUICKY BASICS

The diagram shows a simple basic crystal radio. In the city, with a good antenna, such a set will hear plenty of locals but it is unlikely to hear any DX. Take it out to the campground for the weekend however and even a simple set like this is capable of logging DX. Since most of us live in or near the city, we need to look at ways of transforming the basic set into a DX machine!



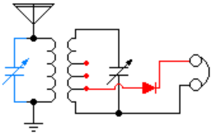
Basic Crystal Radio



Loose-coupled Antenna Circuit

In order to separate the strong locals, the tuned circuit (L-C) must have as high a 'Q' as possible. Placing the diode and headphone load at the top of the circuit will result in strong signals but poor selectivity. The impedance of the headphones will load down the tuned circuit, lowering its 'Q'. The result is very poor selectivity. Tapping the diode/headphone load at a lower point in the tuned circuit results in less 'Q-lowering' of the circuit. The result is a higher degree of selectivity. You don't, however, get a free ride! The higher selectivity diode tap point results in less overall voltage being fed to the headphones. Signals are weaker but easier to separate! The challenge of building an efficient tuner is to find the right balance between selectivity and sensitivity!

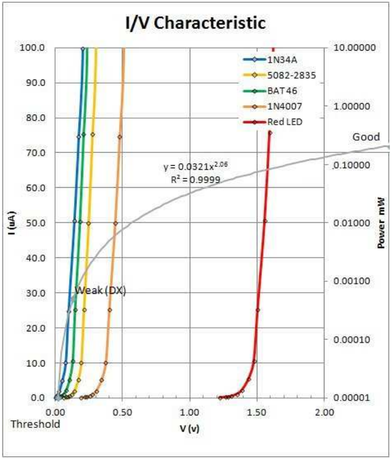
There are a few more improvements that will help the 'basic set'. More sensitivity as well as more selectivity can be realized in the antenna circuit. A separate antenna coupling coil that will couple the antenna into the main tuning coil will result in a further overall improvement. If the position of the antenna coil can be adjusted in relation to the main tuning (detector) coil, a degree of coupling can be reached that offers a good balance point between adequate sensitivity and improved selectivity. Often the antenna coil and the detector coils are mounted on a long rod or dowel that allows easy adjustment of the 'loose-coupling' circuits. Also note that improved detector tuning can be achieved by optimizing the diode 'tap' location on the main tuning coil.



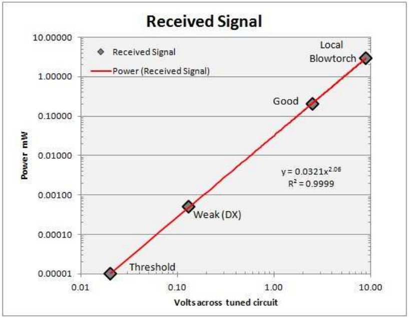
Parallel-tuned Antenna Coupler

Further improvements in both sensitivity and selectivity can be achieved by actually tuning

---

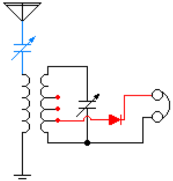


This plot at left takes some actual diode I/V measurements rather than the models presented below and plots them along with the above RF voltage across the LC circuit versus RF power in mW. Here one sees that pushing for very very low Vf (via high Is / low n combinations) pushes the limit of detectable signal power from the antenna. At such minute power levels I imagine the reverse leakage current becomes significant and probably offsets the low operating point gains sought.



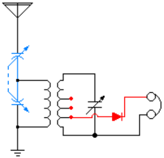
The above is an interesting plot taken from the text discussion in "Crystal Set Analysis" by Berthold Bosch. It presents received signal strength across the tuned circuit for various scenarios from threshold audibility to local blowtorch. This plot should be considered a single example specific to his location and antenna/ground system. In the text he describes his antenna an an inverted L 43m long (140') and 10m high (32'), an excellent antenna most of us do not have the real estate to erect, but offsetting this is a poor ground with Rg = 210ohms. Given the offsetting conditions I would imagine this is a good generic example of what received signal voltage and power levels presented across the LC circuit to the diode are likely to be. Bosch cited 40nV as the threshold of audible detectability (impedance matched conditions with 16kohm RF impedance / 4kohm DC phones) and for this plot I pushed it back to 20nV as it gave a superior regression fit.

the antenna system to resonance. Your type of antenna system as well as the part of the AM band that you are tuning will determine which system works best. The series-tuned antenna coupler is best suited for tuning large antennas, especially those with large horizontal runs ("top hats"). The parallel-tuned antenna coupler is better suited for tuning shorter antennas, such as vertical wires, masts or whips - those without top hats. A series of test clips or a simple switching system can be used experimentally to determine what works best for you. *Making this effort is important as it goes a long way towards avoiding initial disappointment with the crystal set's performance.* Such a system as this is called a 'double-tuned' set. With care and attention to construction, such systems are capable of hearing DX signals.

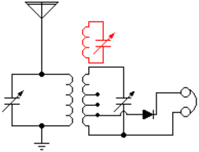


Series-tuned Antenna Coupler

Adding a tuning capacitor in series with the antenna permits a long antenna to be tuned very effectively by a parallel-tuned antenna coupler. In fact, this is the method-of-choice for many crystal set listeners. To avoid the complication of an extra tuning knob, a single-knob, two-gang variable capacitor can be used as shown here. The added variable capacitor can be placed instead in the ground leg. This 'enhanced parallel-tuned' coupler can be very effective in peaking up desired signals while knocking down nearby interference. I have found the use of a tapped coil in this circuit to be very beneficial in achieving optimal Q for the portion of band being tuned. One might even decide on using separate 'high-band' and 'low-band' coils for this circuit.



Enhanced Parallel-tuned Coupler



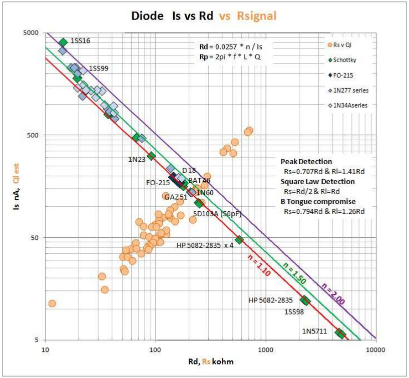
Loose-coupled Wavetrap

Although you may now be able to hear some DX, chances are you are still bothered by at least one (if not several) local 'pest' signals. Further gains in selectivity can be had by the addition of another tuned circuit, called a 'wavetrap'. By coupling this circuit to the detector coil, this

---

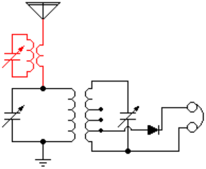
Additionally I have plotted RF signal Rs as orange circles from published coil unloaded Q (see my section on Coil Q). To convert from Qu to Ql I have made the assumption that loaded Q is about 1/5 unloaded Q for low-end sets while in performance sets it may approach 1/2.5 the unloaded Q. This is only an estimate then, but starting from actual data. To make the conversion to Rs I simply plugged the data into the standard equation R = 2pi*f*L*Q using a scaling factor to divide down Qu to Ql from high Q (1400/2.5) to low Q (100/5). This provides a nice visual display of the expected range for Rs in many crystal sets. I plot the Rs against the value of Ql used. Note that these data are for the case at about 1MHz and inductances between 200 and 300uH, as published.

Matching the diode to the tank is a matter of finding a diode with both sensitive qualities (low n) and an Rd close to the Rs presented to the diode (as per Ben Tongue's suggestions for Peak and Square Law detection). Those diodes with Is's in the 100 - 250 nA (100-280 kohm for n=1.1) or so range have the possibility to match while connected to the top of the tank coil without the use of Q-lowering taps, while untapped matching to high-end high-performance big-Litz baskets will require diodes with Is's in the 35 - 60 nA (500-800 kohm for n=1.1) range. Most "typical" germanium diodes have high Is values (>500, >60kohm) and will require a tap. Diodes such as FO-215, BAT 46, 1N60 and GAZ51 can be matched to many tanks without taps. For tanks with high quality Litz coils one will be using HP 5082-2835 or 1SS98 diodes, generally 3 to 4 in parallel to lower the Rd to the desired range. (Curiously, I have not found any diodes with Rd values in the 300 to 4500 kohm range.) Note that both resistance and impedance are frequency-specific so a match at one frequency will not remain matched across the broadcast band.



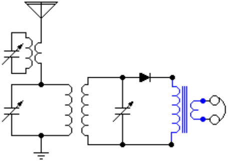
The plot above shows the relationship between diode Is and Rd. Rd is calculated via the equation Rd = VT * n / Is where VT is the thermal voltage = k * T / q = 0.0257V at room temperature and Is and n are from the measured diodes. k is Boltzmann's constant = 1.38E-23 J/K and q is the electron charge = 1.609E-19 coulombs. On such a plot I can show lines of constant n, and plot the values for individual diodes for which I have spent considerable effort to determine the parameters Is, n and Rd (where Is is the diode saturation current, n is the ideality factor, and Rd is the diode resistance). On the plot it should be evident how changes in n or Is impact a diodes' Rd.

circuit can be tuned to the same frequency of the pest signal, absorbing much of its signal-killing strength at the detector, while not adversely affecting the strength of wanted signals. More than one wavetrap may be employed to tackle more than one pest signal. With a high Q wavetrap, very loose coupling is usually best.



In-line Wavetrap

Another method that some find successful is the use of an 'in-line' wavetrap in the antenna circuit. The smaller secondary winding can be wound either on top of the primary or on one end. One or two in-line wavetraps can often be used to effectively knockdown the strong pest signals.



Impedance-matched Output

Another important improvement can be made in the headphone circuit. If you are using the old standard style of headphones (Brush, Baldwin etc) they must be high impedance phones. The modern low-impedance 'walkman' style phones will load-down the detector circuit too much, seriously degrading selectivity and signal strength. Even high impedance phones will cause unwanted loading of the detector circuit. Using a low-loss audio transformer with a very high impedance primary between the phones and the detector will reduce the problem and often great gains in selectivity can be achieved. Look for a high quality audio transformer with a primary impedance of at least 100K ohms and a secondary to match your phones. Try to avoid the small printed circuit transformers used in transistor radios - this is a case of the bigger, the better.

One of the greatest improvements made on my own DX set was changing from a pair of vintage high-quality Baldwin phones to a pair of headphones made from an old Navy 'sound-powered' handset. Most crystal radio DXers are utilizing this style of headphone. They are extremely sensitive! Old handsets are always available on e-Bay and can often be had at a bargain price. Often the earpiece transducer as well as the microphone element are identical and a single handset will yield a nice set of phones. The elements can be removed and placed inside an old set of headphone covers or hearing protectors. I think that going 'sound-powered' was the best single improvement that I was able to make when my DX set was evolving

---

Why know the values of Is, n, and Rd of your diodes?:

by Kevin Smith

http://www.lessmiths.com/~kjsmith/crystal/deyeball.shtml

I have been attempting to get a handle on the main diode parameters Is, n, and Rd and how they impact the operation of a crystal radio. My method of choice is to use a graphical approach, plotting charts where variations between plotted parameters become apparent and easy to visualize. I have developed an interesting chart from the measurements above that compares many diodes with respect to Is, n, and Rd, and to understand how this fits into a matching situation with a fuzzy indication of typical tank impedance limits.

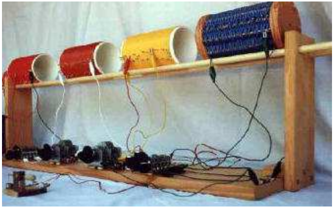
Ultimately one seeks a diode with an Rd that matches with and conjugate to the impedance it sees from the tank (+antenna). In the following discussions I will start with the cross-plot of Is to Rd and then proceed to a look at how received RF power plays a part in the selection and why low Is and n are desired.

OA81 (germanium)	0.0225	800	34
OA95 #1 (germanium)	0.0272	600	45
OA95 #2	0.0221	821	33
OA95 #3	0.0271	604	45
OA95 #4	0.0304	502	54
AA116 (germanium)	0.0441	256	106
AA119 #1 (germanium)	0.0320	461	59
AA119 #2	0.0363	370	73
AA119 #3	0.0428	272	100

The HSMS282K is the same as the HSMS2820, only the HSMS282K has 2 equal diodes in one package.
The Is value of the HSMS282K, the HSMS286K and the 5082-2835 is lower than the value in the datasheet, this has also been noticed by other people.

Ben Tongue wrote me, that the Is value of the 5082-2835 has been reduced over the years by the manufacturer.
Also temperature has big influence, I measured at 18 °C, in datasheets the Is value is given at 25 °C.
A increase from 18 °C to 25 °C will increase the Is by 60 %.

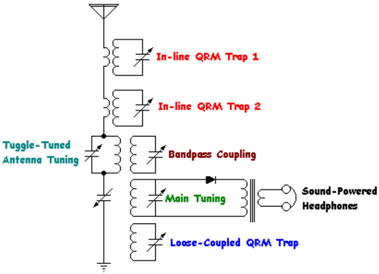
BUILDING YOUR DX SET... Start by thoroughly checking out the many links shown at the bottom of the page. There is a huge amount of good information available on the web. The 'Yahoo Crystal Radio Group' as well as the 'Rap'n Tap' group both provide an interactive forum for asking questions. I would suggest that you consider an experimental loose-coupled test bench. This will allow you to easily make coil changes and adjust coupling between circuits. A fine example of a loose-coupled set is shown below. It was built by Larry Pizzella in San Jose and was used by him to win the 1999 DX Contest!



Although the loose-coupled coil rack is not visible in the photo, my own DX set was built along these same principles.

Many different coil styles, wire diameters and antenna tuning circuits were tried over the space of several months.

This is the schematic diagram of the final arrangement used in my 2002 DX Contest set.



In-line QRM Trap 1
In-line QRM Trap 2
Tuggle-Tuned Antenna Tuning
Bandpass Coupling
Main Tuning
Sound-Powered Headphones
Loose-Coupled QRM Trap

VE7SL - High-Performance DX Crystal Tuner

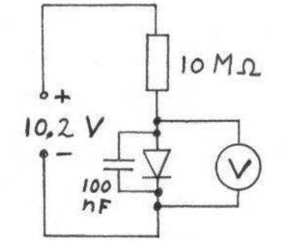
This is a 'triple-tuned' arrangement. There are vernier reduction drives on all tuning capacitors as tuning is very sharp on all circuits. Because of the great abundance of 'blowtorch' signals

More information about measuring the Is you can find on the website of Ben Tongue , in his articles number 4 and 16.

I measured the Is value of several diodes, and calculated the diode resistance RD.
Also some European germanium types are measured.
Several diodes are measured of the type OA95 and AA119

Diode	VD (Volt) at 1 µA	Is (nA)	RD (kΩ).
HSMS282K	0.1341	7.9	3428
HSMS282K 2 parallel	0.118	14.5	1867
HSMS286K (1 diode)	0.1116	18.3	1479
5082-2800	0.1871	1.14	23756
5082-2835	0.1464	5.04	5373
5082-2835 2 parallel	0.1289	9.5	2850
BAT 82	0.136	7.3	3710
BAT 85	0.0686	90.8	298

Measure the voltage across the diode (VD).



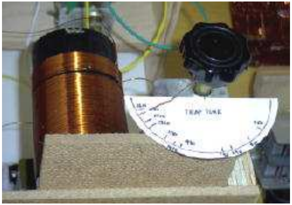
Circuit diagram for measuring the Is value of a diode.
The voltage across the diode is about 0.2 Volt.
The voltage across the resistor is about 10 Volts, so the current is about 1 μA.
The voltmeter must have a resistance of at least 10 MΩ.
The 100 nF capacitor reduces the influence of radio signals and hum on the measurement.

Calculate Is with the formula:

formula 3: Is = ID / (e^ (VD /(0.0257xn))-1)
Is = saturation current of the diode in nA
ID = current through the diode in nA, (1 μA = 1000 nA)
e = base of the natural logarithms, this is about 2.718
^ = raise to the power of
VD = voltage across the diode in Volt
n = ideality factor of the diode, if you don't know this value, take for instance: n= 1.08

within 15 miles of my location (seven 50 KW locals) heavy trapping of pests is required. Both sensitivity and selectivity are good; on evenings of good propagation, signals from Alberta and California can become 'pests' in themselves! Both in-line traps and loose-coupled traps have proven to be very effective.

Not visible in the photo are the in-line wavetraps shown here. Calibrated dials help to quickly zero in on pest frequencies. During the DX Contest 80 different stations were logged on the AM band, the furthest DX catch being WOAI in San Antonio, Texas. U.S. stations in WA, OR, ID, CA, UT, NV, MT and CO as well as Canadians in BC, AB, and SK were heard. Nine 1 KW stations along the west coast were logged as was the little 500 watter CKBX in 100 Mile House, B.C. As well as the DX set performed however, there was still much room for improvement!



BUILDING HINTS

1. Avoid winding coils on wood or cardboard forms. These materials, even when sealed, will absorb 'Q -killing' moisture and impair both selectivity and sensitivity. Use either styrene sewer pipe couplers, thin-walled black ABS plumbing pipe or white PVC tubing. For really high-Q coils, experiment with 'basket-weave' or 'rook' style windings.

2. Avoid small guage wire for coils. Large diameter coils made of solid wire (#12-#18) are easy to wind. Try to space the coil winding so that each turn is at least one wire-diameter away from its neighbor. Stay away from taps if possible. Taps can quickly rob 'Q' from a coil.

3. Make your coils big! No smaller than four inches in diameter is a good starting point.

4. Use the best quality tuning capacitors that you can find. The ones with ceramic insulation are best. Try to avoid mounting them directly against moisture absorbing surfaces, such as wood. Insulate them with ceramic or plexi spacers. Use insulated shaft extensions to avoid hand-capacitance effects.

5. Devise a method of comparing different diodes. A switching arrangement that will accomodate more than one diode will allow some real-time 'A-B' diode comparisons. Test your diodes on a DX signal as a diode that produces the best signal on a strong local may not be the best one for hearing weak DX. Most older 1N34 diodes appear to be hotter than those manufactured today. Consider the use of Schottky diodes that

T = diode temperature
^ = raise to the power of

Ideality factor n

The ideality factor n of a diode indicates how good the diode performs with regard to an ideal diode.
A (not existing) ideal diode has a value of n=1.
At low input signals, the maximum available detected output power is proportional to 1/n.
So doubling the n will halve the output power (this only applies at weak signals).

Diode capacitance

Between the two connections of the diode there will be a certain capacitance (capacitor value), when this capacitance is fairly high (e.g. 10 pF) the tuning range at high frequencies is limited.
At increasing reverse voltage across the diode the capacitance will reduce, also the detected voltage in a crystal receiver is such a reverse voltage.

Through this, the frequency of the circuit can shift upwards when receiving strong signals.
On the next page: experiments with a detector unit you find in table 3 a measurement about the frequency shift.

Measuring the Is value of a diode.

We can measure the Is value of a diode as follows:
Send a small current through the diode, the value of this current (ID) must be about 1 μA.

With 3 diodes parallel, the value of RD shall be divided by 3 etc..

Diode resistance when using bias current.

We can decrease the value of RD by sending a small DC bias current (e.g. 0.1 uA) in forward direction through the diode.
The higher the bias current, the lower RD will be.

With the following formula we can calculate the diode resistance RD, when we make use of a DC bias current.

Formula 2: RD = 0.000086171 x n x TK /(Ib + Is)

RD= diode resistance at certain DC bias current Ib (unit: Ohm)
n= ideality factor of the diode
TK = Temperature in Kelvin (= temperature in ºC + 273)
Ib= DC bias current through the diode in A
Is =saturation current of the diode in A

A diode with a certain RD value at a certain bias current, gives the same receiving performance as a diode without bias current with the same RD.

Influence of temperature on "saturation current: Is"

The saturation current (Is-value) is strongly depending on temperature.
A temperature increase of 1 ºC will increase the Is value by about 7 %.
In datasheets, the Is value is most times given at 25 ºC.
If the diode temperature is not 25 ºC, but another value "T", then we must multiply Is with a factor 1.07^(T-25).

have proven to be extremely sensitive when used in high-Q systems.

6. Don't wait too long before considering sound-powered phones. They are a must if you want to hear the weak ones. Watch e-Bay for some good bargains.

7. Use vernier dials/drives on all controls as the high-Q circuits often tune very sharply. Detector tuning and antenna tuners should have a logging scale so that tuning is repeatable.

8. Get your antenna as high as possible. If it can't be very long, then give it lots of top-loading as shown below.

9. Pay attention to your ground system. Buried wires acting as a ground counterpoise work well. Tie into the copper waterpipe system if possible.

10. Keep notes on your experiments.

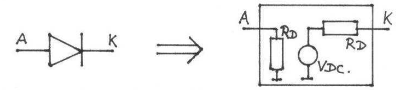
11. Don't give up! Eventually you will break through and hear DX. On nights of good propagation the band will come alive with signals.

The values of n and Is can (sometimes) be found in the diode datasheet.

In the following table some types of schottky diodes, with the values for n, Is and Rd, the maximum reverse voltage and the diode capacitance at zero voltage.

type diode	n	Is at 25 ºC	RD at 25 ºC	maximum reverse voltage	capacitance	
5082-2835	1.08	22 nA	1260 kΩ	8 Volt	1 pF	datasheet
BAT85	?	?	± 200 kΩ ??	30 Volt	10 pF	datasheet
HSMS 2820	1.08	22 nA	1260 kΩ	15 Volt	1 pF	datasheet
HSMS 2850	1.06	3000 nA	9.07 kΩ	2 Volt	0.3 pF	datasheet
HSMS 2860	1.10	38 nA	743 kΩ	4 Volt	0.3 pF	datasheet

To decrease the value RD, we can connect more diodes in parallel, with two the same diodes parallel the value of RD shall halve.



Equivalent circuit of a diode at low input voltages

Via this link you find a measurement on several schottky diodes, which shows detection in the square law region takes place at input voltages below 200 mVpp.

Diode resistance RD.

At zero voltage, diodes have a certain resistance.

This resistance at zero Volt we call RD.

The lower the reverse leaking current of the diode, the higher resistance RD.
When detecting small signals (in the square law region) the input of the diode also behaves like a resistor with value RD.

But how do we know the RD of a diode?

We can calculate it with the formula:
formula 1: RD = 0.000086171 x n x TK / Is
RD = diode resistance at zero Volt (unit: Ohm)
n = ideality factor, the lower this factor the better, between 1.0 and 1.1 is a very good value.
TK = temperature in Kelvin (= temperature in °C + 273)
Is = saturation current (unit: A)
x = multiply

THE CRYSTAL RADIO SET REVISITED

No Author, Smith-Kettlewell

http://www.ski.org/Rehab/sktf/vol11no4Fall1990.html

Abstract

Although this is an article presenting variations on designs of crystal radio sets, I tried to put enough theory in here for universal appeal. For example, impedance matching with transformers is discussed, a formula for calculating single-layer air-core inductors is given, and the "Daniell cell" (a voltaic cell made from a lemon) is also described.

Introduction

[The editor would like to acknowledge the writings and accomplishments of Mr. Joseph Amoros of Richmond, Virginia, who published crystal radio circuits between 1941 and 1953. He sold my father boxes of crystal-set parts when he closed his mail-order business in 1957, and he brought us much joy in experimentation.]

A Bill Gerrish passion is the "crystal set"--the simplest possible radio receiver. It got its name for its crystal detector. Once upon a time, this detector was made by scratching around on a small chip of galena with a rusty wire, hoping to find the happy accident of oxides that would rectify the radio signal and present the amplitude envelope to your headphones.

Actually, various metallic sulfides were used as "crystals." "Galena," lead sulfide or PbS, is the most common ore of lead, and this was often used. "Iron pyrites, iron disulfide or FeS2 (sometimes called "fool's gold") was another ore used. Even Carborundum (a trade name for silicon carbide, SiC) was sometimes employed as the crystal. A blue-steel wire with a sharpened point was the "cat's whisker."

Modern crystal sets use germanium PN-junction diodes for their detectors. These are better diodes than those created from oxides, and they are a lot less fuss.

The purist's crystal radio set is a passive receiver; the power that "runs" it is what you steal from the radio station you are listening to. I leave them connected for years at a time.

With my father's help, I built my first one at age six, and I have hobbied around with them ever since--finding new and better coils now and then, or just putting them in differently shaped containers for the lark of it. The constant faint chatter from earphones hanging on a hook (in my lab upstairs and in the garage) is as friendly as the sound of a familiar clock to me.

Why do I entertain this frivolous pursuit? It's culturally enriching; it causes me to listen to talk shows, music, and yammering advertisers that I would normally leave the room to avoid. I suppose it brings back memories of a kind father revealing his best "shop tricks" to an impatient child who was barely listening.

How Do They Work?

Well, a big long antenna gets in the way of all those waves, and a tuned circuit (a coil and capacitor) resonates to absorb the maximum amount of energy from the station you want--barely attenuating the others. Than comes the heart of the set, the detector.

The power losses in the diode are in this region very low compared to the rectified power.

Situation 2: Recifying in the square law region

If the input voltage is low, lower then the voltage drop of the diode (at 1 mA) then the situation is completely different.
The input of the diode behaves for the RF signal like a resistor with value RD.
The output of the diode behaves like a DC voltage source in series with a resistor, the value of this resistor is also equal to RD.
The value of the DC voltage source is square law related to the amplitude of the RF input signal.
So double input voltage, gives 4 times as much detected DC voltage at the output
In the square law region the output voltage of the diode will be much lower then the input voltage, the diode gives much power loss between input and output.

The lower the input voltage, the higher the losses.
The higher the input voltage, the lower the diode losses.
When further increasing the diode input voltage, we gradually come into the linear detection region.
When receiving weak stations, detection takes place in the square law region.

Between the linear and square law region, there is a region not linear, and not square law but somewhere in between.
This region is not discussed here.

best test several germanium diodes in our receiver and then choose the best. The diode resistance RD of germanium diodes is most times rather low, and only useable in crystal receivers with a low Q (low sensitivity and low selectivity). For high performance receivers, we can better use a suitable schottky diode.

Schottky diodes have a voltage drop of about 0.25 Volt. The differences in properties between two diodes of the same type are often small. Schottky diodes with the correct resistance RD are very useable in high quality crystal receivers.

The given voltage drop is normally measured at a forward current of about 1 mA. Also if we measure the voltage drop of a diode with a multimeter, the test current shall be about 1 mA. But also below this voltage drop the diode can conduct current, and can rectify a RF (radio frequency) signal. Only the current through the diode is then much smaller. When receiving very weak stations, the current through the diode can be e.g. only 10 nA. At such a low current, the voltage drop of the diode is also much lower then at 1 mA.

Detected voltage as function of the input voltage. If we rectify a RF signal with a diode we can distinguish two situations.

Situation 1: Rectifying in the linear region

If the input voltage is high enough (well above the voltage drop of the diode at 1 mA), the output voltage of the diode will be about proportional to the input voltage.

So double input voltage, gives about double output voltage.

The output voltage is almost equal to the peak value of the input voltage.

By itself, a radio signal has no audible component. Stations suitable for this kind of detection have the amplitude of their radio-frequency (RF) signal "modulated" (the power made greater or lesser) by the "intelligence?". (Intelligence on AM radio? Nah!) In order to hear these fluctuations in amplitude, you have to strip away the radio-frequency "carrier" and detect the "envelope" of the amplitude variations.

The diode detector is a rectifier-filter system that feeds the earphones the instantaneous peak value of the RF signal. This peak value is the "amplitude" of the signal, and when you retrieve that information, you get amplitude variations that are the modulating audio.

The rectifier, conducting only in one direction, charges a filter capacitor which then follows the peaks of the RF signal. The filter capacitor is the 0.005uF unit found throughout these circuits, and the diode is the "crystal detector."

Antenna Requirements

The crystal set needs a long antenna and some sort of ground return. A water main is usually the best ground, but a mounting screw of a wall socket, a steam radiator, or a wire fence may be good enough. Avoid using gas pipes as grounds.

There is no substitute for the antenna, however; it must be long. A couple of hundred feet of wire is a luxury. Fifty feet will sometimes do, if it is clear of tall buildings and trees.

My home lab antenna is a continuous overhead central-heating duct which is 50 feet long. (This one is rather funny, too, since it is grounded at the furnace.) My garage antenna is an unused wire in the telephone line. (Be careful of this one. Some telephone installations still use this third yellow wire for the ring signal. first, make sure that there is no DC from the yellow to the red and green, then get someone to ring you and make sure that no high-voltage AC appears between the yellow and the other wires. Finally, always couple to such a thing through a 0.01uF 500-volt capacitor.)

If you can string up a wire antenna, try to keep it from lying on surfaces and bumping into aluminum window frames. You can run a wire antenna inside an attic; hang it from short pieces of string under the rafters (the string acting as insulators). You can use any kind of insulating scheme to keep the antenna from resting against large surfaces. Holding it with plastic strapping of some sort, you can stretch the wire taut between elevated fixtures on a roof so that it doesn't rest on the shingles. On the other hand, unlike transmitting antennas, touching non-metallic objects here and there along the way will not be fatal to an antenna's performance.

That it be long is the important antenna consideration, but beyond this, not having it double back on itself is to be preferred. If you can make it long, but it must go out and comeback, keep the two runs as far apart as possible, and if it can be arranged, avoid running the wire in exact parallel directions.

Luckily, I live where there hasn't been a lightning storm in years. If your situation is otherwise, cultivate the habit of grounding your outdoor antenna when not in use, and if you hear a rumble of thunder, ground it quickly with a clip lead and run like a turkey.

DIODES

Dick Kleijer crystal-radio.eu
http://www.crystal-radio.eu/endiodes.htm

Which diode can I use best in my crystal receiver?

Maybe you think a diode with a voltage drop as low as possible, then also small signals at the detector circuit are detected. But diodes with a low voltage drop, also have a high reverse current (leaking current), this will load the detector circuit heavier, the Q of the detector circuit reduces, and with that also the voltage across the LC circuit. At a lower input voltage the diode will give much more losses, and it can happen that despite the lower voltage drop of the diode, you have less voltage at the load resistor. Besides that, reduction of circuit Q will also gives a less selective receiver.

For every 20 mV less voltage drop, the reverse current will approximately double.

Germanium, silicon, en schottky diodes. Depending on the material they are made from, we can distinguish germanium diodes, silicon diodes and schottky diodes. There are some more types, which are not discussed here.

Silicon diodes have the highest voltage drop (about 0.5 Volt) and are for this reason not very useable for crystal receivers. Unless we use a small DC bias current, which brings the diode already a little bit in conduction.

Germanium diodes have a low voltage drop (about 0.1 - 0.2 Volt) and are often used in crystal receivers. The properties like voltage drop and reverse current can vary a lot between two germanium diodes of the same type. In practice we can

Notes on the Various Components

The crystal set lends itself to parts which have been "scrounged" from far and wide. Don't ever let a dead radio, a 1960-vintage circuit board, or a dead telephone slip through your fingers. From telephones, you can get passably good medium-impedance earphones. From old radios, you can get coils and variable capacitors, output transformers for matching to low-impedance earphones, and cabinets to build your crystal sets into. From old circuit boards with solid-state stuff on them, you can get germanium diodes, or transistors that can be used as diodes. If the family finds the catsup in an orange-juice bottle some day, they will just have to accept the fact that you've used the nice cylindrical plastic catsup squeeze bottle as a coil form.

The Diode Detector

Radio Shack still sells 1N34A germanium diodes--ten for a dollar as cat. No. 276-1123. Mouser also sells germanium diodes--cat. No 333-1N34 and 333-1N60 ($.17 and $.25).

Though not always the case, these diodes are in glass envelopes which break rather easily if you are zealous in bending their leads. Also, their leads are often plated iron, and if you fool around too much in soldering them, the plating will come off, the iron will oxidize, and you will find the process of soldering tiresome, if not impossible. Solder 'em quickly, but deliberately, and treat them gently.

You can use a germanium transistor for its base-emitter diode. Typically, people tie the collector and the base together for one diode connection, and use the emitter for the other connection. If the transistor is burned out, you can often tie the collector and emitter together for one end of the "diode, and use the base lead as the diode's other end.

Silicon diodes and transistors won't work (unless the radio station is breathing down your throat). This is because silicon junctions have a comparatively high forward voltage--typically 0.6V as opposed to 0.3V for germanium junctions. On the other hand, you can apply an external bias voltage to reduce this unwelcome threshold to zero, and a circuit for that is given later.

Another possibility is use of the "Schotky Barrier rectifier"; these begin conducting at 1/3 volt, and they make a loud crystal set. Their disadvantage is that they have a very high capacitance; this is true because they use a large-area metal barrier in the junction. Near 0 volts, their typical capacitance is over 100pF, so use of them means that you have trouble tuning the top of the band. Nevertheless, they are fun to try, and a typical number is the 1N5819.

[You have all heard of the razor-blade detector. You rest a pencil lead (one intended for a mechanical pencil) on the edge of the blade; the oxide inevitably present on the thin edge conducts best in one direction. Like the galena and cat's whisker business, this is not a very good diode, and it's a lot of fuss. Interestingly, it was invented by a prisoner; he probably couldn't get down to Radio Shack.]

Commercially Made Coils

Rather than winding your own coils, you can buy them. The store-bought ones, because there is less market than there used to be, can be quite expensive. Once common place, a ferrite-

Because of the 20 cm distance, there is a loose coupling between the coils.

Connect the probe to the LC circuit.

The earth connection of the probe must be connected to the housing of the tuner capacitor.

The probe is connected to the oscilloscope.

The probe provides a small loading of the circuit, so the Q will not reduce so much.

There are also 1:1 and 1:10 probe's, but these will load the LC circuit too much.

The 1:100 probe I use has a input resistance of 100 M.Ohm, and a input capacity of 4 pF.

The output voltage of the generator must be set so high, that the oscilloscoop gives a clear picture of the RF signal.

Because the 100 times attenuation in the probe, the signal generator output must be set fairly high.

When measuring low Q circuits, I must set the generator output to it's maximum of 20 Volt peak-peak.

For measuring the Q: perform the 5 steps described on the top of this page.

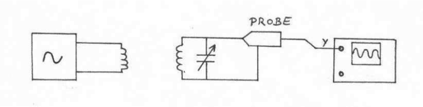
The frequency adjustment is done by hand, by turning the frequency knob of the generator.

point is higher in frequency then f.res, this frequency we call: fh.

Step 5:

Calculate the bandwidth BW: **BW= fh - fl.**Calculate the Q: **Q= f.res / BW**

For performing these 5 steps, we can use the following test setup



In the schematic above you see from left to right the following components.

A signal generator A coupling coil

The LC circuit

A 1:100 oscilloscope probe

An oscilloscope

Connect the output of the signal generator to the coupling coil having e.g. 50 turns.

Place the coupling coil at about 20 cm from the coil of the LC circuit.

The coupling coil don't have to be high Q.

---

slug-tuned broadcast coil, the good-ol' Miller 9001, now costs you $11. (The tapped one, Miller 9011, is nearly $13 now.)

Nevertheless, trying circuits with those Miller slug-tuned coils is worth doing, because they have such a high Q. Besides having the advantage of a ferrite core, they are wound with "Litz wire." [To conquer the "skin effect" (the tendency for RF current to use only the outside surface of a wire), Litz wire is made of many thin strands of wire, all insulated from one another. The result is low resistance at radio frequencies.] Moreover, those Miller coils are "scramble wound"; their turns do not lie parallel to one another, thereby greatly reducing the distributed capacitance.

Store-bought coils have a funny mounting arrangement. They have a springy metal cap that fits into a 0.3-inch diameter hole. A small tab 1/4 of an inch away from center keeps the coil from turning in its mounting as you adjust the slug. The mounting plate must be thin metal--an aluminum chassis or a fabricated bracket.

Homemade Air-Core Coils

It is easy to make your own air-core coils by winding magnet wire, or even wire-wrap wire, around a cylindrical form.

"Magnet wire" is copper wire which has been coated with enamel insulation; enamel is used because it is so much thinner than other insulating materials. You strip its insulation with medium-grade sandpaper; you test to see if you have gotten down to bare wire with a continuity tester.

There are various types of enamel--some very tough and some fragile. For radio coils, it doesn't matter which kind you use.

(These differences are important to electromagnetics people--designers of motors and transformers.)

Radio Shack has an assortment of "magnet wire"; they give you 40 feet of 22-gauge, 75 feet of 26-gauge, and 200 feet of 30-gauge--Radio Shack No. 2781345. Any electronics supplier or electric motor shop can provide you with magnet wire. Belden Wire Company and Vector Electronics Company sell magnet wire by weight--1/2- and 1-pound spools.

For example, Belden Wire Co. sells "solderable magnet wire" whose enamel is destroyed in the soldering process (as long as the soldering is done at 800 degrees or more). This enamel chafes easily, but it is good enough for these coils; it can be gotten from Newark Electronics. A half pound spool of 22-gauge has the Belden No. 8051, Newark cat. No. 36F1314 (about $20, ouch). A half-pound spool of 24-gauge is Belden No. 8052, Newark cat. No. 36F1315. (about $20).

Though it frightens me to tell you this, Mouser has magnet wire, but only in large quantities. For example, they list an 8-pound 22-gauge spool of magnet wire--cat. No. 501MW22H (4000 feet). I bought one; it only cost me $80, and it is very nice wire made by Phelps Dodge. You can use it as antenna wire as well, but that's a lifetime supply for you and your neighbors.
Typical coil forms for the broadcast band are cores from paper rolls--toilet-tissue cores or kitchen-towel cores, cardboard mailing tubes, or plastic tubes (perhaps bottles with the tops and bottoms cut off). Plastic ones are the best; paper and cardboard take on moisture that causes losses and lowers the Q.

MEASURING THE Q OF LC CIRCUITS

Dick Kleijer crystal-radio.eu
http://www.crystal-radio.eu/enqmeting.htm

In theory we can determine the Q of a circuit as follows:

Step 1

Couple a RF signal generator to the LC circuit.The coupling between generator and LC circuit must be loose, otherwise the output resistance of the generator will load the circuit and reduces the Q.

Step 2:

Set the generator to the frequency at which you want to measure the Q.Adjust the LC circuit (turn the tuner capacitor) so you have maximum voltage over the circuit, the circuit is now in resonance, this frequency is the resonance frequency of the circuit (f.res).

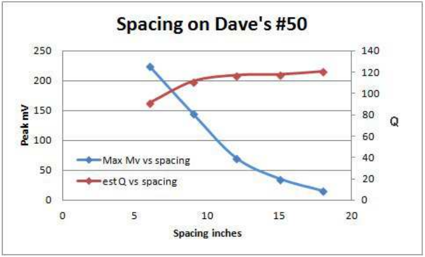
Step 3:

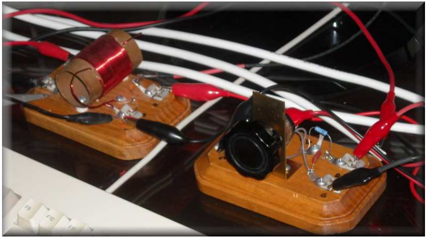
Measure the voltage over the LC circuit at resonance frequency (f.res).

Step 4:

Vary the generator frequency a little above and below f.res. and determine the two frequenties were the voltage over the circuit is 0.707 times the value at f.res.The voltage reduction to 0.707 times, is the -3 dB point.One -3 dB point, is lower in frequency then f.res, this frequency we call: fl.The other -3 dB

Figure 6.





Securing a coil against a panel, especially a wood panel, will cause losses and will add distributed capacitance. Therefore, mount your coils on spacers.

My current favorite plastic forms are the "pill bottles" (vials, 30-dram and 60-dram sizes). These are available from sympathetic pharmacists (you have to convince one that these are for your crystal set).

The 60-dram vial measures 2 inches in diameter--more or less--and 5-1/4 inches long. The 30-dram vial is also 2 inches in diameter, but about 3 inches long (they leave a little room for cotton at the opening). The minor disadvantage of these bottles is the slight taper--smaller at the bottom. Because of the taper, all coils should be wound from the bottom up, so that succeeding turns drift toward the coil, not away from it.

A pill bottle is rather nice for mounting; you just screw the cap to the board and snap the bottle into place so that it stands vertically. This way, spacing the coil away from the board is automatically taken care of.

The ends of windings are anchored by weaving them in and out of a couple of holes. Consider the process of installing a 17-turn antenna winding at one end of a coil form. About 1/2 inch from the end of the form, you poke two holes which are perhaps 1/2 inch apart. You thread the magnet wire through one of the holes--from outside--and pull it through about 8 inches. Then, you poke the wire through the neighboring hole from the inside and pull it taut (giving you 7-1/2 inches of free end now. You now repeat the process; poke the wire down through the first hole and pull it taut, then poke it back out the second hole and pull it taut. This will fix the end firmly in place.

Crumple up the free end and stuff it into the form where it will be out of your way. Next, get a piece of tape ready and stick it to the edge of your workbench where you can grab it handily. Turning the form slowly, wind your 17 turns, every once in a while pressing them together with three or four fingernails so that there are no amateurish spaces between turns. When you are finished (or when you get tired and need to take a break), grab your piece of tape off the edge of the bench and slap it across the coil to hold it in place.

Once the winding has been completed and the tape is holding it, cut the wire to an 8-inch length. Poke two more holes just beyond the winding and weave the free end in and out as before.

Normally, margins of 5/8 inch are left at the ends of the form to permit screw holes to be drilled for mounting. Sometimes, as with the double-tuned circuit using pill bottles, you need to place a winding at the very end of the form; in this case, passing the first half-turn through another pair of holes opposite the ones fixing the end of the wire will keep wraps from spilling off the end of the form.

As an example of anchoring the end-most turn, consider the problem of winding 20 turns of wire around a plastic soda-bottle cap (making a coupling coil for some of these circuits). Very near the closed end of the cap, two pairs of holes are drilled, diametrically opposed. The wire goes in and out of the first pair and is pulled through to a length of 10 inches; then, the end is woven in and out of the opposite pair of holes to firmly "fix the end." A ridge at the open end of the cap means that the last turn can be anchored in one pair of holes; there is no danger of turns falling over the ridge.

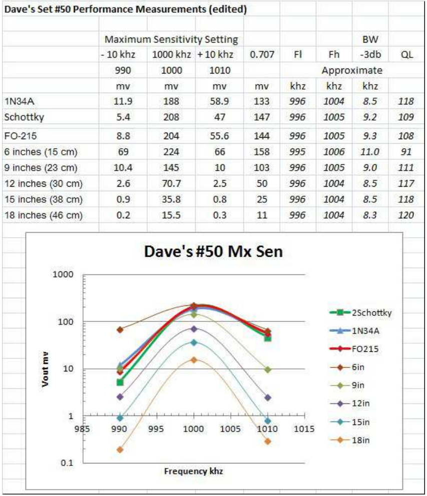
In figure 5 above I have attempted to cast Dave’s measurements into something similar to what I am doing, which is looking at the -3db BW and Q at 1100khz. I finally produced the above spreadsheet where I simply smoothed the data for the 1000khz case and estimated the bandwidth at -3dB. This makes a LOT of assumptions of course. Mostly I assume that the +-10khz measurements are well above the resonance skirt so my smooth curve is not unreasonable.

The #50 set then appears to have, at 1000khz, a -3db bandwidth of around 8-11khz depending on diode and/or spacing between the tank and antenna unit giving loaded Q's of 91-125. These numbers fall in the range of what my own data lead me to expect. Ken Kuhn's page on Resonant Circuit suggests the "typical" QL at 1Mhz ranges between 20 and 100 and Dave’s #50 set is certainly beating the best of that.

In the final figure 6 I have taken my estimated results above and looked at how Q and peak voltage (assuming constant conditions other than the spacing between the antenna and detector units so this ought to reflect power as well). It is quite apparent that the set is rapidly losing output power while Q improvements are flattening out as the spacing between tank and antenna tuner grows to 18 inches. It would appear that a -3db loaded Q of 125 is near the limit of what can be expected in a crystal set.

skill, experience and usage of the best ($$$) materials available. I take this to be just about the most of what can wrung out of the sky with a crystal radio. Dave’s protocol is rather different from my own and he did not make a specific -3dB bandwidth measurement so what I do from here on takes many liberties with his work, my sincere apologies in advance!

Figure 5.



Dave's Set #50 Performance Measurements (edited)

	Maximum Sensitivity Setting						BW	
	- 10 khz	1000 khz	+ 10 khz	0.707	Fl	Fh	-3db	QL
	990	1000	1010		Approximate			
	mv	mv	mv	mv	khz	khz	khz	
1N34A	11.9	188	58.9	133	*996*	*1004*	*8.5*	*118*
Schottky	5.4	208	47	147	*996*	*1005*	*9.2*	*109*
FO-215	8.8	204	55.6	144	*996*	*1005*	*9.3*	*108*
6 inches (15 cm)	69	224	66	158	*995*	*1006*	*11.0*	*91*
9 inches (23 cm)	10.4	145	10	103	*996*	*1005*	*9.0*	*111*
12 inches (30 cm)	2.6	70.7	2.5	50	*996*	*1004*	*8.5*	*117*
15 inches (38 cm)	0.9	35.8	0.8	25	*996*	*1004*	*8.5*	*118*
18 inches (46 cm)	0.2	15.5	0.3	11	*996*	*1004*	*8.3*	*120*

You will see that most of the coils in these circuits require a tap one-quarter or one-third of the way up from ground. A tap can be arranged in two ways. The most elegant way is to sand a little bare spot in the wire when you get to that point in the winding, and solder a pigtail of insulated stranded wire to this bare spot. The other way, while it is a little more crude, is to bend the enameled wire double for an inch or so, then twist it several times so that a loop will emerge from the windings at this point in the coil.

Of course, you can have as many taps as you want. This is one way to match the detector most properly to the earphones--getting sufficient voltage to drive the earphones, while preserving the Q by minimizing the load from the earphones.

When it comes to connecting the coil into the circuit, cut the ends to slightly longer than the desired length and sand about 3/4 of an inch bare and make the connections. If the tap is a twisted loop, don't cut it, but just sand the end of the loop bare and make that connection. Test all stripped segments with a continuity tester; you cannot feel whether you have gotten down to copper, or just roughened the enamel.

Traditional dimensions for radio coils is to design them in such a way that the diameter and length are nearly the same. (Having the length equal the diameter makes the so-called "square coil" which is popularly used.)

There is an approximate formula given in the Reference Data for Engineers, copyright 1964 by IT&T, by which you can calculate the inductance of single-layer coils within a few percent. This expression is:

L (inductance in microHenries) equals n squared times r squared, divided by the quantity 9 r plus 10 l.

Lower-case "l" is the length of the coil in inches, "r" is the radius in inches, and "n" is the number of turns.

For the broadcast band, we want the inductance to fall somewhere around 220 microHenries. To save you the algebra, a 2-inch-diameter form will require secondaries of 80 turns of 22-gauge wire, 77 turns of 24-gauge wire, or 70 turns of 26-gauge wire.

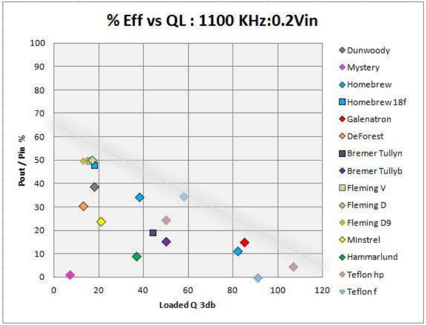
[Because the 60-dram and 30-dram vials are tapered, it is good to make the windings 5% too long to compensate for this.]

Notes on Wire Gauging

The copper wire gauging system used in the U.S. is "the American Wire Gauge" (AWG). The wire diameter changes by a factor of 2 every 6 gauges. Thus, since 26-gauge wire is 0.016 inches in diameter, 20-gauge wire is 0.032 inches in diameter, and 32-gauge wire is 0.008 inches. (These are approximate dimensions, and the enamel adds perhaps 0.001 inches.) Since cross-sectional area depends on the square of the radius, this area changes by a factor of 2 every 3 gauge sizes.

Now, if you can remember three wire sizes, you no longer need a wire table. Good-ol' 22-gauge wire (0.0253 inches in diameter) reminds me of my micrometer--25 thousandths per turn, or 40 turns per inch. Wire of 24-gauge (0.0201 inches) gives you 50 turns per inch. Wire of 20-gauge is about 32 thousandths.

Figure 4.



Here is the bottom line, Q verses Sensitivity, efficiency in this case. On this plot it is readily evident that I have built my fair share of loser radios, but also a good number of sets which push boundary of what can be achieved in terms of compromise between Q and sensitivity. Looking at the plot it is fairly easy to imagine a sloping line or zone running from 0 Q at 60% efficiency down to 120-130 Q at 0% efficiency. Beyond this one will probably never go with tank and antenna tuner alone. It will be time to start adding traps to your bag of tricks. Recall that the above is for the 1100khs frequency and that Q is a function of frequency.

In order to explore this final conclusion, I have taken a look at Dave Schmarder’s excellent bandwidth analysis of his #50 contest set. This set is a superb work of craftsmanship and optimal load resistances for this case was similar to or lower than that for the 0.2Vpp input case.

With all that said, the plot in figure 2 is messy but the impression is that of increasing Q with increasing Rl. I view the plot as having a number of small groupings of measurements with similar conditions, each showing higher Q's associated with higher load resistance.

Figure 3.

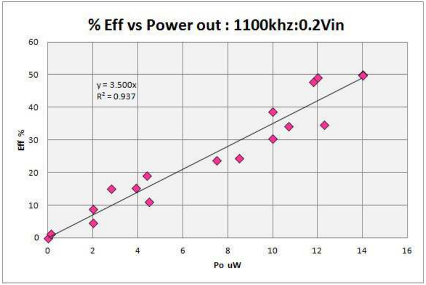


Figure 3 is most obvious with the clear benefit of good set efficiency on output power. An efficient set will better approach the maximum power transfer desired. High Q plays a part here. Still, there is always the tradeoff between selectivity (high Q) and sensitivity. An efficient set delivers more power to the load, but to go after Q you will ultimately be sacrificing sensitivity.

Tuning Capacitors

These are the most hard-to-come-by items in our modern age. Big radios don't have mechanical tuning any more, and little radios will soon give it up. The best tuning capacitors are being harbored in antique radios. Built into metal frames, they have a stationary set of plates ("stator") and a movable set ("rotor"). Many of these are multi-section--usually dual.

Unfortunately, most of the dual ones do not give us two usable sections, because the sections are different sizes and values. The smaller one, used to tune the local oscillator in superheterodyne sets, can be ignored and only the large one used. However, some low-budget radio makers of the 1950s used dual variable capacitors whose sections are identical; for double-tuned crystal sets, these are worth "breaking and entering" for.

Because many salvaged capacitors are fitted with dial-cord pulleys instead of knobs, you may end up making a knob for the odd-sized shaft after the pulley has been pried off.

The rotor is usually common to all sections. Since it is usually part of the frame, and since you must operate it with your hand, it is grounded. Connection to the rotor is almost always done via a mounting screw; solder lugs on the frame are rare. Each stator almost always has two solder lugs, one on each side of the stator, and these are electrically identical.

Radio Shack doesn't even have a suitable capacitor. The only one they show of sufficient range is a "compression-type trimmer" that you have to tune with a screwdriver.

The most readily available modern tuning capacitor is a Mouser unit suited for pocket radios. It has two main sections that go from 5 to 266 picofarads, and four 7pF screwdriver-adjustable trimmers which we can ignore for these sets. The Mouser cat. No. is 24TR218 ($2.71). The only trouble is that they don't supply a knob for the accursed thing; you have to make your own and secure it with a 2.6mm metric screw.

This Mouser unit is festooned with solder lugs. Two sets of three long ones are for the trimmers, which we don't need. There are three short lugs, two on one edge and one on the far corner of an adjacent edge. The lug which is off by itself goes to the rotors of both the large sections; the two coming out the same edge are the stators of these sections.

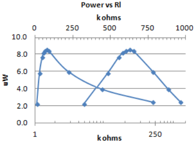
You can mount the Mouser capacitor by sticking its one free edge--or its back--to the chassis or breadboard with double-sided foam tape.

The required range is perhaps 30pF to 365pF. Actually, most go slightly higher than this--400pF or so, and their lower limit can be nice and low--5pF for each section of the Mouser ones. The Mouser units require that you connect the two main sections together, giving you 10pF to 532pF. The important thing is to have enough range to cover the whole broadcast band (given that the coil will have a lot of distributed capacitance).

(For double-tuned sets with matching coils, the Mouser units can be hooked up another way. Two of their 2-gang units are used; the rotors are connected together, the stators of Section A of the two units are connected together, and the stators of Section B are connected together. In this way, you have ganged capacitors; they both have to be at maximum to tune the bottom of the band, and they both have to be minimum to get to the top of the band.)

---

a generic transformer that would work well with many or all minus the complicated switching.

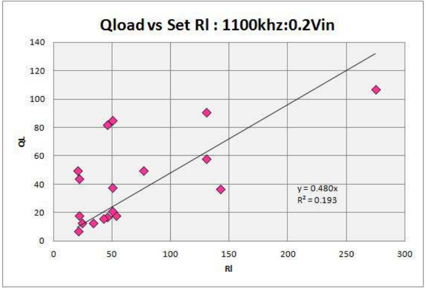


In my testing protocol therefore, I included the important step of determining the optimum load resistance for the set under test conditions. I certainly part company with the school of thought that says to test all sets exactly the same way, including same diode (1N34A typically) and same test load. Sets are designed to work best when impedance matched and at the back end that generally means a load matched to the tank/diode combination that delivers the maxumum power. At right above I show a small plot where I varied the load resistance over a wide range and calculated the output power of the set. (I give the plot with both a linear and a more appropriate log scale). This should demonstrate the importance of optimizing the load resistance.

Optimum load resistance depends on both the tank Q and that portion of the diode detecting the signal. That in turn depends on the signal level. Very weak signals will be rectified in the square-law region of the diode characteristic and require relatively high (and variable) load resistances. Normal to strong signals will be rectified primarily along the peak-detection portion of the diode characteristic and require lower load resistance with less variation. Not shown in the above spreadsheet, I also ran measurements with a 2.0Vpp input. With this stronger signal, rectification was taking place farther out on the diode characteristic. As expected, the measured

If you are serious about getting DX and doing a lot of heavy lifting, you will need a good antenna tuner as part of your set design.

Figure 2.



At the back end of the set things get a bit messier and are not east to show with a simple two-component plot. Here I have chosen to highlight the importance of the proper load resistance on the set loaded Q. In my set testing I have tried to pay close attention to the importance of the load on the tank and diode. Early on I considered construction of an output transformer unit that would work with different radio's as well as with different phones. Such a design can be found on Ben Tongue's excellent and highly technical web site. The plans were well beyond what I was able/willing to take on so I turned my attention to discovering just what load resistance exactly do my sets require for maximum power transfer. After all, if I found only a small range typical values, I might design

Caution: When you transport or store open-frame variable capacitors, be sure that the plates are fully meshed. If a capacitor is partly open, the plates of the rotor can be easily bent out of shape.

LC Resonance

As any radio ham knows, the expression for resonance, whether it's a series- or parallel-tuned circuit, is:

f equals 1 over 2 pi times the square root of L times C.

L is the inductance in Henries, C is the capacitance in Farads, and lower-case f is the frequency in Hertz.

Consider the example of 220 microHenries and 400 picoFarads. Expressed in scientific notation, the capacitor is 4 times 10 to the minus 10th power, and the coil is 2.2 times 10 to the minus 4th. Their product is 8.8 times 10 to the minus 14th. The square root of this is 2.97 times 10 to the minus 7th (you have to divide the exponent by 2 when you take the square root). Multiplying this by 2 times pi (2 times 22/7ths), we get 18.7 times 10 to the minus 7th, or 1.87 times 10 to the minus 6th. The reciprocal of this is 0.535 times 10 to the 6th Hz (the exponent changes sign when you bring it up into the numerator). Ten to the 6th Hz is a megacycle, so the result is 0.535 megaHertz.

Earphones

These are becoming a troublesome item to get, but I've solved it. Crystal sets require high-impedance earphones. By high-impedance, I mean 2,000 ohms or more. Most of the traditional hobby types were electromagnetic; a permanent magnet put a bias on a diaphragm by pulling it in a bit, and then coils around the poles of the magnet would cause the field to fluctuate, causing the diaphragm to move back and forth.

Sometimes seen in junk collections, brands to look for are Trim, Brandes, Telephonics, Cannonball, Scientifics, Baldwin, and Utah. Short of these, you can use the earpieces from broken-down telephone handsets--fashioning a headband as best you can. Trim "Dependables" used to be issued by the Library of Congress for talking book listening. If you know someone who has those, get them somehow, even if you have to rough 'm up a bit.

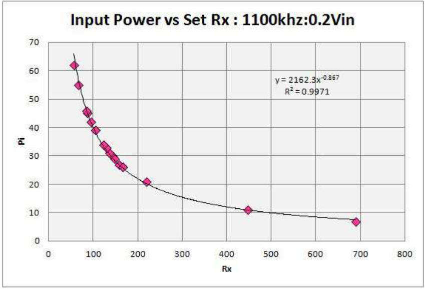
Military surplus phones, such as those made by Utah, were all medium-impedance--600 ohms. These and telephone earpieces must be coupled to the crystal set via an autotransformer (described herein).

Another type, which affords high impedance, is the so-called "crystal earphone." Older ones used a crystal of "Rochelle Salt" as a Piezo-electric element to drive a foil diaphragm. Old ones of these are most likely bad now; the Rochelle Salt takes on moisture and loses its properties over time. New ones have ceramic elements.

They don't look resistive; they electrically appear as capacitors. For this reason, the diode detector may have to be provided with a load resistor in order to perform well. Finally, if you have some around and you are playing with active circuits, you should know that crystal earphones are destroyed by DC, so other than on your crystal sets, put a resistor across these earphones and capacitively couple them.

From the data above some interesting observations can be made.

Figure 1.



In figure 1 above I show the relation of the input power versus the set resistance. The quality of the fit reflects that fact that this is largely a calculated value, but it does illustrate the importance of having a low input impedance to match that of the antenna. This is not often considered in discussions on impedance matching but is critically important. The antenna has an impedance in the 25 - 50 ohm range, not easy to get this in a set without quality parts and construction. My sets typically have an input impedance in the low 100’s ohms and only two of my sets really get down to the 50-60 ohm range giving a good match to the antenna. Both of these are double-tuned sets with a tuggle front end.

The above table of measurements were made at a nominal frequency of 1100khz and input voltage of 0.2Vpp as indicated on a digital signal generator following the protocol outlined. I give the radio name under test should you wish to refer to my pages for more on each set. The columns as follows:

Vin = 0.2V pp (0.71mV rms)
Pin = input power in uW into the set (after the dummy antenna)
Pout= output power across the load resistor in uW
% Eff = 100 * Pin/Pout
BW = bandwidth in khz at -3db
Ql = calculated loaded Q of the set
Rx = the set input resistance presented to the antenna
Rl = measured optimum load resistance for maximum power transfer
Rd = Diode junction resistance Rd used in the set

Mouser has high-impedance "crystal earphones," Mouser No. 25CR060 ($1.56). In general, pairs of magnetic earphones are connected in series to get their impedance as high as possible. Pairs of crystal earphones are connected in parallel. Earphones of the wrong impedance can be used if you match the impedances with transformers. For example, small loudspeakers can be used if you drive them with an audio-output transformer; the speakers, connected in series, go to the low-impedance secondary of the transformer (a 4- or 8-ohm secondary), and the primary winding goes to the earphone connections at the crystal set. Medium-impedance earphones, such as telephone receivers, can be matched with an autotransformer; if you have an output transformer with a center-tapped primary winding, the medium-impedance earphones, connected in series, go between the center tap and one side of the winding, while the whole winding goes to the earphone connections on the set (the secondary of the transformer is left open).

Impedances are transformed by the square of the turns ratio. For example, when you drive medium-impedance earphones with half the winding as described above, you see four times the earphone impedance across the whole winding.

Anyhow, I made a pair of earphones using two 8-ohm 2-inch loudspeakers connected in series (an earphone impedance of 16 ohms). Then, I used a miniature output transformer--8 ohms to 1.2K--to drive them. (The series-connected speakers are connected across the 8-ohm secondary winding, while the 1.2K primary goes to the earphone connections on the set. If it has one, the centertap on the primary is unused.) Since the secondary is looking at 16 ohms, the impedance appearing across the primary is 2.4K. I glued the speakers to stiff cardboard disks, then covered the backs with disposable drinking cups. The headband was fashioned out of coathanger. They could further be improved by putting foam shrouds to seal around the ears, thus improving acoustical coupling.

I tried my best to make "Walkman" earphones work, but to no avail. Since they are open earphones, and have small diaphragms, they are somewhat inefficient.

Mouser has a fine output transformer for matching to low-impedance headphones (like my PM speakers and drinking cups); it has a center-tapped primary of 20K, and a center-tapped secondary of 4 ohms--Cat. No. 42KM019 ($1.63). A less drastic impedance-matching transformer is the 8-ohms to center-tapped 1.2K--Mouser No. 42KM003.

Vacuum-tube radios have salvageable transformers of two types, center-tapped primaries for 2-tube "push-pull" amplifiers and high-impedance nontapped primaries for "single-ended" circuits. I kind of remember that 10K to 3.2 ohms was common.

Try everything--half the primary, the full primary, and try various output taps if the transformer has them.

Crystal sets don't give you much surplus power, so acoustic coupling to the ears is a critical factor.

Matching the Detector and the Earphones

Since the impedances of earphones you are likely to find are "by guess and by gosh," and the Q they are effecting is largely unknown, matching by experimentation is the best approach. The following effects can be noted to aid in troubleshooting:

11) Adjust the frequency above and below f res until the output level falls to the level calculated in step10 above. These frequencies are f high and f low. Record these.
12) The -3dB bandwidth = f high - f low. Loaded Q (QL) = f res / BW
13) Take the generator output peak-peak voltage recorded in step 2 above and convert it to rms voltage as follows: mVrms = mVpp / 2.829. This is Lauter's RF voltage E1 mV.
14) Measure the RF voltage across the 10 ohm resistor on the dummy antenna. This is Lauter's RF voltage E2 mV.
15) Input current to the dummy antenna = Lin = E2/10 (mA)
16) Input power to the dummy antenna = Pin = E1 * Lin (uW)
17) Power loss in the dummy antenna = Pda = Lin^2 * 25 (the dummy antenna resistance)
18) Power delivered to set = Px = Pin - Pda uW
19) Set input resistance = Rx ohms = Ex / Lin where Ex = E1 - (Lin * 25)
20) Set output power (uW) = Pout = Vout^2 / Rl in ohms
21) Set % efficiency (sensitivity) = 100 * Pout / Pin

Having built a fair number of sets, and with varying quality, all the above protocol was developed to test my sets. What follows now is a discussion of how my sets stack up against each other and some notes on what one may expect in a crystal radio performance-wise. I give a summary table below of the essential data gathered on each of my sets.

Table 1

Once I find the optimum load resistance, I set the pot to that and proceed to the main testing for sensitivity and bandwidth/Q measurements.

Test Protocol as follows:

1) Connect the set to be tested between the dummy antenna and measurement load as per the above diagram.
2) Connect the signal generator to the dummy antenna and set the frequency and voltage output. I typically test in the center of the BCB at 1100khz and use a 200mVpp output sine wave.
3) Set the load resistance to somewhere around 50k ohms. The exact value is not critical as it will be adjusted later.
4) Connect the DVM and tune the set to peak the output voltage. Care here is amply rewarded, especially with double-tuned sets.
5) Once peaked it is necessary to adjust the generator frequency to re-peak the output voltage as hand-capacitance or other factors may have prevented perfect tuning. You now have your set properly tuned for maximum output. Presumably this also means the best possible impedance match between the set and dummy antenna. This is the resonant frequency (f res).
6) Record the frequency and output voltage.
7) Now find the optimum load resistance. This is done by making a series of paired measurements of load resistance and output voltage. Power in uW = mVout * Rl khoms.
8) Set the load resistor pot to the value where power output is highest, this is the optimum load for the test. Record this.
9) With the signal generator re-peak the output voltage and re-record the resonant frequency (f res) and output voltage (Vout mV).
10) Multiply mVout by 0.707 to find the -3dB level.

If the set distorts on weak stations, either the diode is not seeing enough voltage (the tap is too low), or the impedance of the earphones is too high and the detector is not sufficiently loaded. If the set is nonselective ("broad as a barn"), the impedance of the earphones is loading the coil and greatly reducing its Q, or the tap is too high on the coil.

3DB tapping:

The serious experimenter will want to build his secondary winding with a selection of taps for the detector. Since the impedance--and the power--go up as the square of the turns ratio, adopt the systematic scheme of doubling the impedance every tap (going in steps of 3dB). This would require taps at the following percentages of the winding (starting at the grounded end): 18%, 25%, 35%, 50%, 70%, and the full winding. Notice that these percentages are related to each other by the square root of 2; the voltage and current either go up by 1.414 or down by 0.707 as you select neighboring taps, while the impedance and power are either doubled or halved as you select neighboring taps.

Solder these taps to successive positions on a 6-position rotary switch. The arm of the switch will then go through the diode, then through the earphones to ground, with the earphones being shunted by 0.005uF (see the circuits to follow).

Crystal Radio Circuits

I give my impression of the performance of any set I have in my collection. I tested them on my little furnace duct antenna, doing so in the daytime.

Some of these have variable coupling between the antenna and the main tuning coil. This creates a sort of combination volume control and selectivity adjustment. In general, the looser the coupling, the more selective the set becomes, although this is at the cost of sound volume. If a station is blustery enough to over-ride all interference, tighten the coupling, turn it up and dance to it.

* * *

I won a science prize once for making the world's smallest receiver. The circuit follows:

Circuit for the World's Smallest Receiver

The antenna goes through the diode to ground. The earphones are in parallel with the diode.

It gets everything all at once. This can be rather fun. You can hear zealous spiritual leaders in shouting matches with "rap musicians." When a famous politician's speech is carried by all the networks, you can hear three or four of him, all accompanied by drum machines.

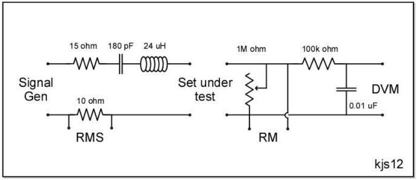
[It is worth noting that at one time, this was good enough; in the very early days of radio, all the stations were trying to transmit at a wavelength of 300 meters--all more or less at 1 mHz.]

* * *

Perhaps the most common of circuits uses the distributed capacitance of the coil to make a half-baked LC circuit. A long coil is required, perhaps 200 turns of No. 26 wire on a cardboard or plastic form (such as a mailing tube, the core from a roll of kitchen towels, or the 60-dram vial). Then, for mechanical stability, "dope" (coat) the coil with model cement. By sanding to and fro with medium sandpaper, create a strip of exposed copper across the windings so that a metal "tuning slide" can make contact with the coil. Next, fashion some sort

radios to be tested a 1N34A diode and then use a standard 2k ohm load resistance to make the output measurements. This may give a standard and comparable result, but it does not insure a good impedance match and does not reflect the intended usage and setup of many crystal sets, especially sets intended for high-performance. Here I am interested to learn just what is the optimal load resistance for my set under the test conditions. Note the caveat "under the test conditions". This may not reflect actual usage unless you take precautions. You will want to set the generator to an input voltage similar to what you expect the radio to receive in actual operation. You will probably want to signal level work the diode in its peak-detection region but not so high as to saturate the diode, (In making a loaded Q measurement you want to make sure that the diode impedance stays constant; otherwise, the change in diode impedance (as the tank attenuates the signal before the diode) will change the load on the tank and the bandwidth measurement won't really reflect the Q of the tank). Finally, for the output voltage you need a good voltmeter with very high input impedance that will not load down the set under test. This really means a good DVM. I use a used Keithley 192 bench meter with a 2M ohm input impedance, and as a backup a used Keithley 180 bench electrometer. Overkill perhaps, but for just in case...

Getting back to the load resistance then, my protocol is to find the optimum resistance to deliver the maximum power (not voltage!) to the load. This is a bit of a tedious process but will amply rewarded. Having tuned and peaked the set to the measurement frequency, I then take a series of resistance/voltage readings to find the maximum power output. In my circuit this is accomplished with the variable 1M pot. The resistance meter and voltmeter cannot be connected to the load at the same time making this a tiresome road to follow.



For the tests I originally found an old analog signal generator on ebay which I sadly found to be wholly inadequate. The unit was by no means cheap but the dial was difficult to read with any precision and the "play" in the dial made readings hopelessly inaccurate. Finally, it gave no indication of the attenuation or voltage output levels, rms or pp, of the signal. I have since found a nice, reasonably-priced new digital unit, (max's out at 2Mhz so strictly for AM band work) that gives good readings, gives me the output voltage level in pp, and can even produce different wave forms. I recommend if you are seeking to equip your lab, go this way from the start!

To calculate the signal input power you will need a good rms voltmeter. This is a non-trivial item and, after my experience with the vintage signal generator I was leery of getting a used meter. In any case, an expensive dedicated single-use piece of equipment seemed extravagant. For this measurement I have found entirely acceptable results using an oscilloscope which, of course, is useful for so much more and belongs in your lab regardless!

It is on the back end of the measurement where I diverge from Lauter's protocol significantly. He recommends placing in all

---

of slider (perhaps a ground-off hacksaw blade anchored at one end) which can be used to make contact with the bared coil windings anywhere along the length of the coil.

What you have created is a coil with adjustable length. Only one end of the coil is connected to anything; the other coil connection is the slider. A circuit for the simplest tuned set is as follows:

Simplest Tunable Crystal Radio

The coil slider is grounded. One end of the coil goes to the antenna; also connected to this end of the coil is one end of the diode. The other end of the diode goes through the earphones to ground. The earphones are shunted by a 0.005uF capacitor.

The disadvantage of this circuit is that it is broad as a barn--for two reasons. First, the tuned circuit is low Q because of the resistance of all that wire used in the coil; tuning the set with a variable capacitor means that a shorter coil could be used. Second, no attempt is made to efficiently match the earphone circuit to the "tuned circuit"; unless very high-impedance earphones are used, the load that they present lowers the Q even more.

* * *

Standard LC-Tuned Crystal Radio Circuit

This was copied from a Knight Kit (Allied Radio) set purchased in the 1950s. The variable capacitor goes from 22pF to 400pF. It uses a Bakelite coil form measuring 1-1/2 inches in diameter and 5 inches long. The coil, wound with 22-gauge magnet wire, has a primary (antenna coupling) winding of 17 turns placed at the cold end of a secondary (main tuning) winding of 120 turns. The detector is taken from a tap which is one-fourth the way up from the cold end-- of the secondary30 turns from the grounded end. The separation between the two windings is 1/4 inch.

The antenna coil, 17 turns of wire at one end of the form, has its outside end going to the antenna, while the end nearest the secondary is grounded, This end of the secondary is also grounded. The other end of the secondary goes to the stator of the variable capacitor; the rotor of the capacitor is grounded. A tap on the secondary which is 30 turns from the ground end goes through the diode, then through a 0.005uF disc ceramic capacitor to ground. The earphones are connected across this ceramic capacitor.

This can be built on a 2-inch coil form; just change the proportions. For example, 80 turns of 24-gauge wire--or 85 turns of 22-gauge wire-- on a 2-inch-diameter form will do; I like the detector tap to be at 25 turns. The antenna primary can stay at 15 or 17 turns; an embellishment is to wind a 25-turn antenna winding with a tap 9 turns away from the antenna end, using two antenna binding posts for selectable coupling.

This set is very selective, but not very loud. I am able to get ten stations, seven of which can be isolated enough to listen to. It can be jazzed up a bit by providing it with variable antenna coupling:

Variable Coupling on the Standard Set

Wind 20-turns of 26-gauge wire on the plastic cap of a plastic soda bottle. Affix this cap to a nonmetallic stick of some sort, and fashion a sliding arrangement that permits the cap to be moved in and out of the grounded end of the secondary

---

RADIO TEST

Kevin Smith
http://www.lessmiths.com/~kjsmith/crystal/rtest.shtml

OK, now that you have built a radio, or several, how do they perform? Without a bit of objective testing you will never really know. I have often read descriptions of radio performance such as "tunes very sharply" or "separates two closely spaced stations" and/or etc. These are qualitative descriptions that do not really give you much information. To know your radio, it takes some measuring. I am making the assumption here that, as a homebrew radio builder, you will find tinkering and measuring your sets just as interesting as their design and construction.

For testing, I have pretty much lifted the excellent procedure outlined by Charles Lauter with a few modifications to suit my own philosophy. I will give my own protocol but first let’s look at the needed equipment and test setup. Testing a crystal set requires two pieces of homemade equipment, a dummy antenna in front of the set which allows measurement points, and a measurement load at the back end. Other pieces of equipment include a signal generator, an rms voltmeter, a resistance meter, and a good digital voltmeter. Circuit schematics for the homebrew components are shown below.

automatically. These measurements will definitely determine which are the best Xtal sets, circuits, or components.

Happy Testing

---

winding--from an inch separation to where the coupling coil is encircled by the cold end of the secondary.

Scrap the 17-turn antenna winding on the main coil form. One end of the bottle-cap coil is grounded, while the other end goes to the antenna.

Popular Mechanics Variation

A variation on this basic circuit appeared in the January 1977 issue of Popular Mechanics. The coil was wound on a "salt box" (3-1/4 inches in diameter). The junction between the antenna coil and the tuned secondary is a tap on an overall winding--14 turns below the tap for the antenna coil and 32 turns above the tap for the secondary.

This "tap" is grounded. The antenna goes to the end of the 14-turn segment. The rotor of the capacitor is grounded. The stator goes to the end of the 32-turn segment. The end of the 32-turn coil also goes through the diode, then through the earphones to ground, with the earphones being shunted by 0.005uF.

The editor has not built this Popular Mechanics set, but the closeness of its primary and secondary windings--delineated only by a tap on the continuous coil--will probably make for a loud set with poor selectivity.

* * *

A Double-Tuned Crystal Radio Circuit with Variable Coupling

Two 2-inch-diameter 30-dram pill bottles (vials) are used. The bottoms and caps are drilled to accommodate a wooden dowel or plastic rod. One of the vials is fixed by winding tape around the rod inside the bottle and under its cap; the other is permitted to slide a distance of perhaps 2 inches. When moved toward one another, the vials must be able to touch bottoms.

Matching coils are wound on the vials--85 turns of 22-gauge or 80 turns of 24-gauge wire. These are started as close to the bottoms as you can get, so that they can be brought quite close together. The secondary is tapped 25 turns up from the bottom, or even better, taps are placed at 15 turns, 20 turns, 28 turns, 40 turns, and 56 turns. (If multiple taps are created, connect them to successive positions of a 6-position rotary switch, with position six going to the hot end of the full winding.)

The rotors of two 400pF variable capacitors are grounded. The antenna goes to the far end of the untapped coil; the bottom of this coil goes to the stator of one of the capacitors. The bottom end of the tapped coil is grounded, with its top end going to the stator of the other capacitor. The tap (or the arm of the rotary switch) goes through the diode, then through the earphones to ground. The earphones are shunted by 0.005uF.

Because the coils are matched (except for the load the detector puts on the secondary), you can get away with a ganged 2-section variable, although having separate variable capacitors gives you some freedom to "detune" the set as an aid to interference elimination. Remember, the two sections of a ganged tuning capacitor must be identical.

With this set, I was able to receive ten stations, eight of which could be isolated well enough to listen to.

* * *

2. Increase the Signal Generator output until the DVM reads 1.414 volts DC. This will now be the new value for the input voltage "E1". Maintain this value for the rest of these tests.
3. Decrease the effective Xtal set coupling until the DVM reads 1.000 volts DC. This may effect the Xtal set tuning. If so retune the Xtal set to the Signal generator frequency and repeat steps two and three. Remember to keep E1 constant.
4. Again measure the bandwidth using the previous method above. Now go back and measure the sensitivity again.
5. This process can be repeated over and over for better and better selectivity.

This bandwidth will be less (narrower) than when the Xtal set was adjusted for maximum output.

Xtal Sets with more tuned circuits and variable coupling will have in better selectivity.

Now lets see what this reduced coupling did for the Type SCR-54-A. The bandwidth at -3db is now only 9 kHz and the -20 db bandwidth is now 73.6 kHz. Lets see what this change did to sensitivity. Crystal Set efficiency decreased from 21.5% to 12 35% and total efficiency decreased from 6.83% to 3.67%. These efficiency numbers were expected because they are about a -3db decrease which is the same as the decrease in step 3 above.

The set of three measurements above is then repeated at each of the test frequencies listed above.

All of the above measuring may sound like a lot of work but once the equipment is in place the tests do not take long to perform. I use a computer spreadsheet so that after I enter the measured values, all of the calculations are performed

Now lets again look at the little "Beaver Baby Grand " Xtal Set for Selectivity.
F test = 600.4 kHz, F low = 543.4 kHz, F test - F low = 57 kHz, 57 kHz x 2 = 114 kHz. This is the Basic or "-3db" Bandwidth. Now "F min" = 434 kHz, F test - F min = 166.4 kHz, 166.4 kHz x 2 = 332.8 kHz = the "-20db" Bandwidth.
As you can see this is not a very selective Xtal set. For the intended use, this was probably not a problem in 1922. In today's world, the Set would be receiving several stations at the same time in almost any city in the US.

Now lets look at the selectivity of the Type SCR-54-A. F test=600 kHz, F low= 589.3 kHz, F min = 556 kHz. This means that the half power or -3db bandwidth is 21.4 kHz and the -20db bandwidth is 88 kHz. With this Set we have the ability to possibility select a station we want to listen to.

BANDWIDTH AT REDUCED SENSITIVITY:

More complex Xtal sets have some means of improving Selectivity at the expense of Sensitivity. There are a number of ways of accomplishing this. In most cases reducing the coupling between the antenna circuit and a second tuned circuit is the method used. This is the purpose of the "Loose or Slide Coupler" that is used in many of the better Xtal Sets. In some Sets changing a coil tap and re-tuning a capacitor will accomplish the change in coupling. It may require some experimenting to find the best adjustment method and control settings for any given Xtal Set. The procedure is as follows;
1. Set up the Signal Generator and the Xtal set the same as in the sensitivity measurement above.

A Slug-Tuned Crystal Radio Circuit Using the Tapped Miller Coil

This is quick to build. The Miller 9011 tapped variable inductor is used. (This tap is 30% up from the cold end.) The end of the smaller portion of the winding is grounded. The other end goes to the stator of a 400pF variable capacitor, the rotor of which is grounded. The antenna goes to the tap. The tap also goes through the diode, then through the earphones to ground, with the earphones being shunted by 0.005uF.

The slug is adjusted to "center" the band in the range of the tuning capacitor. Simpler yet, since the coil is variable, the capacitor can be a fixed one--330pF across the ends of the coil. The only disadvantage is that the range of inductance is only about 4 to 1; since the frequency varies as the square root of this, the frequency range can only be 2 to 1 (from 0.6 to 1.2 mHz, for example).

This set is very loud; however, because the antenna coupling is much too high, it's broad as a hippopotamus. Four stations were received, and only three could be isolated enough to listen to.

A profound improvement can be had by fashioning a coil for the antenna. Wind 20 turns around a plastic bottle cap from a soda bottle (which is 1-1/8 inches in diameter). With bee's wax or cement, fix the cap over the end of the Miller coil. On this new primary winding, the end nearest the open end of the bottle cap is grounded; the other end goes to the antenna.

Wow! With this arrangement, I received eleven stations; eight could be isolated enough to be listened to.

Double-Tuned Crystal Radio Circuit with Slug-Tuned Coils

The coils, one Miller 9001 and one Miller 9011 are mounted near each other on a strip of aluminum. They are pointing the same direction and mounted at 1 inch between centers. (One could make this coupling adjustable by using two strips of aluminum in a scissor-like arrangement, but moving these coils detunes them, so you would have to adjust their slugs each time.)

One end of the 9001 (untapped) coil goes to the antenna; its other end goes to the stator of one section of a dual-ganged variable capacitor. The rotors are grounded. The end of the smaller portion of windings on a Miller 9011 coil (tapped at one-third) is grounded; the other end of this coil goes to the stator of the second variable section. The tap on the 9011 goes through the diode, then through the earphones to ground, with the earphones being shunted by 0.005uF.

Back the slugs out 15 turns from maximum (maximum being all the way in). Check to see if the capacitor tunes the whole band; if not, move the slugs in to shift the stations downward, or move them out to shift every thing upward as necessary. Next, find a station near the top of the band and adjust the secondary (the tapped coil) for maximum volume; retune the capacitor and adjust the slug a second time.

This is the best set I've ever had. It's quite loud, and I can receive thirteen stations, eleven of which can be isolated enough to listen to.

DVM and again adjust the Generator above value of "E1". Keeping the value of "E1" constant removes the output resistance of the Signal Generator and keeps it from effecting the bandwidth to be measured. The higher the resistance or impedance of the Signal Generator the more interaction there will be to obtain the final value frequency at which the Xtal Set output is 0.707 Volts DC. This is because as the Set is tuned to other than the selectivity test frequency the impedance looking into the dummy antenna (the Signal Generator load) changes. >>> Keep the value "E1" constant for this and all of the following tests. <<< Note the frequency. Call this frequency "F low".

2. Subtract "F low" from the Sensitivity test frequency used above. Multiply this difference frequency by two. This value is the basic (half power) "-3db" Bandwidth " of the Xtal Set for comparison purposes. Normally one would measure the frequency above the peak or resonant frequency at which the output also drops to 0.707 Volts and then subtract F low from this frequency to obtain the bandwidth. This measurement was done in this manor because in some cases if you try to increase the frequency to the point where the output voltage drops to 0.707 Volts a number of resonant frequencies of the Xtal Set will prevent obtaining a good measurement. (usually due to self resonance of the Xtal Set coil or coils) The error due to this method is very small.

3. For the next test, reduce the Signal generator frequency until the Xtal Set output voltage decreases to 0.1 VDC. (-20db). Call this frequency "F min"

4. Subtract "F min" from the Sensitivity test frequency above. Multiply this difference frequency by two. This is the "-20db" Bandwidth.

editions of Crystal Clear by Maurice L. Sievers and was described by Alan Douglas in the September 1978 edition of Radio Age.
Test frequency used = 600 kHz. Measured values; E1 = .605 VRMS, E2 = .048 VRMS.
Now the computed values; Iin = .0048 A, Pin = .0029 W, Pda = .000576W, Px = .00233W, Pout = .0005W, The Xtal Set efficiency = Pout / Px = 21.48% <<<<< Now lets add the dummy antenna. Rx = 101 Ohms, Pbest = .0073W then the total efficiency is 6.8%. It is Interesting that there is more energy or power loss in the set but the total efficiency is better by about 4.3 times. This Set has more coils and capacitors which is why the losses are greater but the sets ability to better match the antenna is the reason that the overall efficiency or sensitivity is better. The set is much more selective as will be shown below.

SELECTIVITY or BANDWIDTH:

These tests are a little more complex than the sensitivity tests because selectivity is more complex to define.

Make the sensitivity measurement above and before making any adjustments to
the Xtal Set or to the Signal Generator output level make the following measurements. I recommend using a frequency counter to measure the following frequencies.

1. Decrease the Signal Generator frequency to below the first test frequency and until the Xtal set output decreases to 0.707 volts DC (-3db). Readjust the output level from the Signal Generator until the value of Voltage "E1" is the same as that used above. Again adjust the frequency for 0.707 VDC on the

Circuit for the "Rocket Radio"

If you happen to find one of these in a junk shop, they're a lot of fun. They use an untapped slug-tuned coil. Pulling up on the nose of the rocket withdraws the slug and raises the frequency. You will notice the conspicuous lack of the filter capacitor; the capacitance of the crystal earphone doubles as the filter.

One end of the coil goes to the antenna. This junction also goes through the diode, then through the earphone (high-impedance crystal earplug) to the other end of the coil. The earphone is shunted by 220K. Depending on the make, the coil might have enough windings so that the distributed capacitance is the "C" of the LC circuit. Some had a capacitor shunting the coil.

The only ground return is you. The main secret behind these radios was the intimate acoustic coupling from the earphone to your tympanum.

* * *

A Hybrid Crystal Radio Circuit with Lots of Adjustments

The secondary winding is an air-core coil--85 turns of 22-gauge on a 2-inch form; it is multiply tapped and the detector is taken from a 6-position switch. The primary is a Miller 9001 untapped inductor. Since the characteristics of the coils are markedly different, you need separate variable capacitors (of identical type).

The Miller coil is mounted on a sliding bracket that allows its penetration into the cold end of the secondary to be adjusted. A knob is made--having a 4-40 threaded hole--and is fitted to the screw of the slug; a "jam nut" ahead of the knob secures it firmly.

The antenna goes through the Miller coil, then through C1 to ground. The bottom end of the secondary is grounded and C2 is across this coil. The taps go to positions of a rotary switch. The arm of this switch feeds the detector.

Adjusting the slug changes the Q of the primary. Sliding the primary in and out changes the selectivity and the volume. Selecting taps optimizes the match to the detector (changing the selectivity and the volume). Juggling the capacitors finds optimal settings to cope with various interference.

The tally isn't in yet on its performance; the instrument is too hard to run. I'm still chasing the last of thirteen stations, and I think I imagine a fourteenth. Watching you operate it can really impress your sister, although, in my high-school days, it seemed to invoke little enthusiasm from girl friends.

* * *

The 15-Minute Set Using RF Chokes

Mouser sells a style of miniature RF choke which has "radial leads"--both leads come out one end. This set uses two of them, Mouser cat. No. ME434-1120-221L (220 microHenries). If you butt them together--head to head--and hold them together with tape, you have the makings of a fine double-tuned crystal set. I "haywired" the whole arrangement on one side of an old open-frame ganged variable capacitor (no board was used). On the other hand, these chokes, together with two of the Mouser 24TR218 variable capacitors, could be put into a fancy little package.

The antenna goes through RFC1 to the stator of C1. The rotors of C1 and C2 are grounded. RFC2 is in parallel with C2. The

The resistance of the dummy antenna is 25 Ohms. The ideal resistance of the Xtal Set is also 25 Ohms. This means that the best possible efficiency of a Xtal Set and its antenna and ground is 50%. This would mean a Xtal Set that is 100% efficient. Compute the power into the Dummy antenna if Rx was 25 Ohms; P best = (E1 x E1) / (25 + 25).
h. Now compute the total efficiency of the Xtal Set with the dummy antenna. Total efficiency = Pout / P best <<<<<<<<<<<<

Now lets look at some numbers from an actual Xtal Set. The set is "The Beaver Baby Grand vest pocket Radio Receiving Set". This is a little set that was made in 1922 and is shown on the cover of the book "Crystal Clear - Volume 2" by Maurice L. Sievers.
Test frequency used = 600.4 kHz. Measured values; E1 = 1.26 Vrms, E2 = .015 Vrms Computed values; Iin = .0015 Amps, Pin = .00189 W, Pda = .0000563 W, Px = .00183 W, Pout = .0005 W, Xtal Set efficiency = Pout / Px = 27.27% <<<<<<
Now for the rest of the story; Rx = 815 Ohms, P best = .0317 W, and the total efficiency Pout / P best is now only 1.57%. As you can see, the efficiency of the set alone is not too bad, but when it is used with a standard antenna it is very poor.
This set was apparently designed as a low cost Xtal Set to receive a one and only nearby Radio Station. This Set is an example of no matter what type of coil or coil wire is used, the performance would not change enough to matter.

Now lets look at a better Xtal Set. The set is from world war one and its U.S. Army designation is "Type SCR-54-A". This set is also known as a BC-14A. The Set is shown in both

2. Set the Signal Generator to produce an output level of about one volt rms.
3. Adjust the Xtal Set for maximum output as indicated by the DVM.
4. Adjust the Signal Generator frequency for maximum output that may be slightly different from the nominal test frequency due to the inability of the Xtal Set to precisely tune if the Set uses coil taps for tuning.
For extremely accurate tuning make the phase of the voltage across the 10 Ohm resistor in phase with the Signal Generator output using a two channel Oscilloscope.
5. Adjust the Signal Generator output level to give a 1.000 volt DC reading on the DVM.
6. Measure the RF Voltage at the input of the Dummy antenna. Call this value "E1".
7. Measure the RF Voltage across the 10 Ohm resistor. (Between the Signal generator common and the Xtal Set ground terminal) Call this value "E2".

8. Now some calculations;
a. Compute the input current: Iin = E2/10 (Amps)
b. Compute the power into the Dummy antenna; Pin = E1 x Iin (Watts)
c. Compute the power loss in the Dummy antenna: Pda = (Iin x Iin) x 25
d. Compute the power going into the Xtal Set: Px = Pin - Pda
e. The power output from the Xtal Set = Pout = Eo x Eo / 2000 = 0.0005 Watts
f. Now for the Xtal Set Efficiency = Pout / Pin = .0005 / Pin <<<<<<< Note that this value does not include any mismatch with the Dummy antenna.
g. Compute the Xtal Set input Resistance. (Assuming that Xtal Set is tuned)
Rx = Ex / Iin , where Ex = E1 - (Iin x 25)

stator of C2 goes through the diode, then through the earphones to ground. The earphones are shunted by 0.005uF.
I declare, when I counted ten stations on this set (eight of which I could isolate), I jumped right up to "Do the Locomotion" with my soldering iron.

[These chokes are nifty. Good for 50mA, values we are likely to use elsewhere are also available: 2.2mH are ME434-1120-223K, and 10mH are ME434-1120-104K. The "L" appending the low-value 220uH unit stands for "low."]

* * *

Biasing the Detector

Crystal detectors have a serious flaw; a station must be strong enough to overcome a forward voltage drop before it begins to drive the earphones. This can be compensated for with a bias battery. Moreover, someday, germanium diodes may be unavailable; active circuits are taking their place (creating "perfect rectifiers"). A silicon diode, such as the 1N914, can be used if you get rid of its 0.6V forward voltage drop.

"Battery?!" you cry in protest. It's not so bad, in that the current drain is only 15 microamps; a D cell will last its shelf life. This detector will work in any of the sets.

Biased Detector Circuit

The tap on the coil goes to the cathode of a 1N914 diode. To provide the detector with a DC load, the anode goes through 22K, in parallel with 0.005uF, to ground. The anode also goes to the positive end of a 1uF electrolytic (tantalum is best), with the negative end of this cap going through the earphones to ground. The junction of the earphones and the electrolytic goes to the negative terminal of a cell, with the positive of the cell going through 100K to the diode's anode.

Selectivity is quite different, a number of definitions are required. The most basic and popular definition of bandwidth is the so-called half power or "-3db" bandwidth. To obtain this number subtract the frequency below the frequency of maximum output where the output decreases to 0.707 times the peak value (F below) from the frequency above the maximum output frequency again where the output decreases to 0.707 times the peak value (F above). Or bandwidth = (F above) minus (F below) In the actual tests below I modify this definition slightly to simplify the measurements.

Selectivity has a second and important characteristic. It is related to Shape Factor. Filters are what make any Radio selective. Unfortunately simple filters are far from perfect. If a filter were perfect the bandwidth would be the same for all values of attenuation. The term Shape Factor refers to a bandwidth at a greater attenuation than -3db. For our tests we will use the bandwidth at -20db for comparing different Xtal Sets. (-20db = E max. x 0.1) & (-3db = E max. x 0.707)

I could also define the out of band selectivity in terms of Filter Skirt Slope (db / octave) but I decided not to go there. I am also not going to talk about circuit quality or "Q" because there seems to be a lot of confusion as to its meaning in overall Xtal Set performance.

Lets Test!!

SENSITIVITY OR EFFICIENCY TESTS:

Finally we are ready to make the Crystal Set Sensitivity or Efficiency measurement as follows;

1. Set the Signal Generator to the first test frequency. (unmodulated)

All Crystal Sets produce a DC output voltage that is proportional to the RF input level and this same proportionality applies to modulated signals producing audio output signals. Proof of this is too long to present here.

Test setup:
Set up the test equipment, the test circuits and the Crystal Set as follows; Connect the output of the unmodulated Signal generator to the 15 Ohm resistor in series with the 200 pF capacitor in series the 20 uH coil. Connect the other end of the coil to the Antenna terminal of the Crystal Set. Connect the low or ground output of the Signal Generator to the 10 Ohm resistor. Connect the other end of the 10 Ohm resistor to the Low or Ground input terminal of the Crystal Set. Note; This Crystal Set terminal is often not in common with (connected to) either of the output terminals. Place the Crystal set on an insulated surface such as a book for RF isolation purposes.

Connect the precision 2000 Ohm resistor across, or in parallel with, the headphone terminals. Connect the 100 kOhm resistor to one of the headphone terminals. Connect the other end of this resistor to one input of the DVM. Connect the other headphone terminal to the other input of the DVM. Connect a .01 uF capacitor in parallel with the DVM. Place the DVM and all DVM leads on a second RF insulated surface like another book.
Replace galena or other diode types with the 1N34 type. I use clip leads.

Test definitions or characteristics definitions:
The only item that I had to define so far were the values for the Dummy antenna. Efficiency by general definition is the ratio of the power output of any device to the power input to it or Pout / Pin.

DESIGNING AN AIR-CORE INDUCTOR

by Kenneth A. Kuhn

http://www.kennethkuhn.com/students/crystal_radios/designing_inductors.pdf

Introduction

This chapter describes the mathematical process for designing an air-core inductor comprised of a single layer solenoid winding over a rigid coil form. Although the development of the mathematics is a bit complicated the final result is simple to apply. For practical reasons, this chapter will make use of English rather than metric units. A well designed and constructed air-core coil has better performance than those with ferrite cores. Ferrite acts as a flux multiplier and has the advantage that the physical size of the inductor can be reduced. That is very important for small radios and the chief reason ferrite is used. The price paid for small size is loss of performance but that loss is generally negligible in active radios. The loss is not bad for crystal radio performance and many good crystal radios have been built using ferrite core inductors. But ferrite is not required. Purists correctly argue that the coil should be air core as that is how early radios were built. A mediocre ferrite core inductor will work considerably better than a poorly designed air-core one and that has probably led to the popularity of ferrite as the process for designing good air-core inductors is not widely known. This chapter reveals those secrets.

Analytic equation

The classic equation (which you can find in any book or article about winding inductors) for calculating the inductance of a given single layer coil is (Reference 2):

$$L = \frac{r2*n2}{9*r + 10*l} \qquad \text{Eq. 1}$$

where:
L = inductance in microhenries
r = coil radius in inches (center of coil to center of conductor)
n = number of turns
l = coil length in inches (center of starting turn to center of ending turn)

This equation is generally accurate to around one percent for inductors of common dimensions. It is more convenient to work with coil diameter and Equation 1 can be written as:

$$L = \frac{d2*n2}{18*d + 40*l} \qquad \text{Eq. 2}$$

where d is the coil diameter in inches (center of conductor to center of conductor)

Example: What is the inductance of a coil has a diameter of 2.5 inches, a length of 2.33 inches, and has 72 turns?

$$L = \frac{2.5*2.5*72*72}{18*2.5 + 40*2.33} = 234 \text{ uH}$$

Development of design equations

Equations 1 and 2 are fine for determining the inductance of an existing coil but are very awkward to apply to the design of a desired coil as there are many variables. Any time there are a multitude of variables then the possibility of optimum combinations or relations should be explored. In the following development the number of variables is reduced by finding

recommended by the IRE in 1930 for general radio testing. The circuit consists of a 25 Ohm resistor in series with a 200 pF capacitor in series with a 20 uH coil. I split the 25 Ohm resistor into a 15 Ohm resistor and a precision 10 Ohm resistor. The 10 Ohm resistor is connected between the low or ground side of the signal generator output and the input ground terminal of the crystal Set. This was done so that input current to the Crystal Set can be easily measured. The input current is then equal to voltage measured across the 10 Ohm resistor divided by 10.

The second test circuit is the Crystal Set output load that will be used in place of headphones. Headphones all have three values of impedance; the first is simply the DC resistance, the second is the AC impedance at audio frequencies, and the third is the AC impedance at RF frequencies. In order to remove the characteristics of different headphones from the tests I simply replace the headphones with a precision 2,000 Ohm resistor. In these tests I am only interested in measuring the DC output voltage from the Crystal Set so a simple low-pass filter that does not effect the output voltage is added. It is simply a 100 kOhm resistor in series with the DVM and a .01 uF capacitor in parallel with the DVM.

Test frequencies:

The following are the test frequencies to be used. They are 400, 600, 800, 1000, 1200, 1400, and 1600 kHz. Many of the older Crystal sets will not tune to frequencies above 1000 kHz but do as many as the set can tune. This next aspect of the tests may confuse some people. All tests to be conducted are made using an UNMODULATED input signal. This increases the accuracy of the tests and eliminates the need for a Signal Generator that can produce an accurate percentage of modulation. (Most Generators cannot)

Test equipment:
The first item to consider for testing is the test equipment. These tests require three pieces of test equipment; a RF Signal Generator, a RF Voltmeter, and a Digital Multimeter. The Signal Generator should have low output impedance. Most Generators by HP, GR, and others have output impedance of 50 Ohms. When terminated this impedance drops to 25 Ohms. Many so-called Function Generators that have a Sine Wave Output will work just as well for these tests. The impedance does not matter for the sensitivity tests but can be factor in the selectivity tests. The RF Signal generator does not need to have any modulation capability at all. A less common piece of test equipment is the RF Voltmeter. This meter must be able to measure RF voltages from a few milliVolts to over one Volt. A high input impedance of over 10,000 Ohms is also required. A well-calibrated Oscilloscope will meet these requirements but will be less accurate. I use a HP model 3400A RMS Voltmeter. The third piece of test equipment is a battery powered 3-1/2 digit Digital Voltmeter (DVM) or Digital Multimeter (DMM). Everyone that does anything electrical or electronic should have one of these. The DVM must be battery powered to make it RF isolated from ground. Standard diode or diodes need to be used. Some sets use two. I decided to use the popular and common 1N34 type germanium diode.

Test circuits:
The next items are two simple test circuits. The first is the circuit to connect the Signal Generator to the Antenna and Ground terminals of the Crystal Set. This circuit is known as an "Artificial Antenna", "Dummy Antenna", or "Standard Input Circuit". Its purpose is to simulate a typical "Long Wire" or "Marconi" antenna so that the Crystal Set can be tuned in the normal manor. The values chosen to be used are those

relations to known constants. We first replace the coil length by a factor that relates it to the diameter.

$$l = k*d \qquad \text{Eq. 3}$$

where
l = coil length in inches
k = a dimensionless constant
d = coil diameter in inches as before
Substituting Equation 3 into Equation 2 gives:

$$L = \frac{d2*n2}{18*d + 40*k*d}$$

which reduces to

$$L = \frac{d*n2}{18 + 40*k} \qquad \text{Eq. 4}$$

It can be shown that the value of k that minimizes the length of wire to wind the coil is 0.450. However, other research indicates (see Reference 1) that the value of k that minimizes coil losses is approximately 0.96 even though that value uses about twenty percent more wire. Factors contributing to coil losses include:

- * Ohmic losses in the wire including skin-effect
- * Dielectric losses in the coil form and nearby materials
- * Dielectric losses in the insulation around the wire
- * Induction losses in nearby materials

There are also losses caused by adjacent turns being too close together. It has been found (see Reference 1) that the optimum spacing (wire center to wire center) of adjacent turns is between about 1.3 to 2.0 times the diameter of the conductor. Coils for crystal radios are commonly wound using what is known as magnet wire (thin enamel insulation) and the turns are tightly wound next to each other corresponding to a spacing factor slightly greater than 1.0 (the thin insulation is of finite thickness). Although it is less than the optimum discussed it works well.

Without some special technique (such as a lathe) it can be very difficult to manually wind a coil with controlled spacing between the turns. One easy method for achieving a spacing factor of 2.0 is to wind two wires tightly side by side at the same time and then remove one of the windings when finished. Smaller spacing factors can be achieved using a smaller diameter wire for the spacer but the difficulty of controlling two wires will increase. It might occur to someone to use a wire with a thicker insulation so that a spacing is naturally formed with a tight winding. The problem with this method is that the insulation may increase dielectric losses and become self defeating –although this may be a small issue –be sure to try it before tossing the concept. This method can work great if Teflon wire is used as that is a very low-loss material and the internal wire strands are silver plated.

Equation 4 can be used to determine the optimum coil diameter for a given inductance and wire size. We note that the coil length is the number of turns divided by t (turns per inch of the wire). We also note that the coil length has previously been related to the coil diameter by the constant, k. Thus:

$n = k*d*t$ Eq. 5

Substituting Equation 5 into Equation 4 gives:

CRYSTAL SET TESTING

Charles A Lauter. (email: Lautron@aol.com)

Background:

The following are standards and methods for testing Crystal Sets for the purpose of comparing the performance of different Crystal Sets, Crystal Set circuits, and Crystal Set components in an objective manor. Standards for testing all other types of radios have been in effect since about 1930. Crystal Sets have been in use for almost 100 years but no performance measurement standards exist that I can find. I have read many-many claims of performance for various circuits, coil types, wire types and so on but all without performance numbers that have been measured. There are only two parameters or characteristics of all Crystal Sets that are important. They are the sensitivity or efficiency and the selectivity or bandwidth characteristics. The ability of a Crystal Set to match its antenna is very important and I am including it with the efficiency or sensitivity characteristics. These tests cover Sets designed to tune all or most of the AM broadcast band of frequencies using a standard antenna. More about the antenna below. I am not measuring characteristics such as extended tuning range or the ability to work with very long antennas or any other features not common to most Crystal Sets. In all fairness, these tests were very difficult or impractical to perform back in the 1920s or earlier. Today these tests can be performed with what I consider a modest investment in test equipment. These tests will allow me to compare my collection of Crystal Sets with each other and with other designs of circuits and components. They will also permit comparison with other people's Sets and designs. The reasons for the following test equipment and test circuits will become apparent as the test procedures are followed.

loudness. Similarly, two 3 dB steps would be sensed as "equal" changes in loudness.

$$L = \frac{k2*t2*d3}{18 + 40*k} \qquad \text{Eq. 6}$$

We will use 0.96 for k and t will be that of the particular wire we have available. Solving Equation 6 for the optimum diameter gives:

$$d\_optimum = 4*(L/t2)1/3 \qquad \text{Eq. 7}$$

Figure 1 shows a plot of this Equation 7 for common wire sizes. In all cases the turns are close-spaced. The lower curves are for common enamel insulated magnet wire. The two upper curves are for vinyl insulated house wire which can be considered if a large diameter coil form is available. To use the curves, select the desired inductance and the wire size that will be used. Look up the optimum coil form diameter and then use the closest practical form you have to that size. The optimum is broad so do not worry about being exactly on it. Note that the true diameter is the sum of the diameter of the coil form and the diameter of the wire since by definition the coil diameter is measured between opposite centers of the wire.

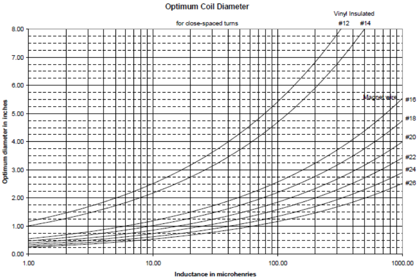


Figure 1: Optimum coil diameter

The following table provides typical values for t (turns per inch) for some common wire sizes:

Table 1: Wire data

Gauge	t	Comments
12	6.2	Vinyl insulated house wire
14	7.7	Vinyl insulated house wire
16	19	Enamel insulated magnet wire
18	24	ditto
20	31	ditto
22	39	ditto
24	50	ditto
26	62	ditto

The length of the winding will be the number of turns divided by the turns per inch of the wire. That is:

---

know how much better (or worse) a change to it is, and can express it in deciBels (dB). Say that you are taking voltage measurements across a resistor as I do. If the voltage goes from 20 to 40 milliVolts, the ratio of voltages is 2; but wait. Power varies as the square of voltage, so the power ratio is 2 squared, or 4. The logarithm of 4 is 0.6, and 10 times that is 6, or 6 dB. Incidentally, if the measured voltage had gone down from 20 to 10, you would have gone down by 6 dB - it works in both directions. So, all you have to do is divide the larger voltage (or current) by the smaller, square the result (this is your power ratio), and multiply the logarithm of that number by 10 to get the change in dB. Round your answer to the nearest whole number.

If this seems like too much work, here is a short table of common power ratios, the corresponding dB change, and what it means to your ear:

Power ratio	dB	Effect
2	3	barely detectable change
4	6	noticeable
5	7	a little better than 6
10	10	oh yeah
20	13	a smidgen better than 10
100	20	oh yeah again -
200	23	(just to show you the effect of multiplying two numbers by adding their logs)

Note: to the ear, an increase of 10 dB, followed by an increase to 100 dB above the original power level (another 10 dB increase) would be sensed as two equal step increases in

Sony is tuned to just as the cap is closing. That is the minimum f for the LC. More tweeking will determine what f the LC will tune as it is coming fully open. Those 2 f indicate the frequency range of that coil and cap combination.

This will work for MW BCB (midwave broadcast band) using a MW transistor radio, but be sure that the coil on the internal ferrite antenna is parallel with the coil under test.

DECIBELS FOR DUMMIES (how to sound like a tekkie)

The ear is a marvelous device which can process a wide range of noise levels. At a frequency of 1000 Hz, the weakest sound detectable is at a power of about 1 picowatt per square meter, normal speech is about at 1 microwatt, hearing damage starts at about 1 milliwatt (smoky bar with a loud band), and physical pain is felt at 1 watt. Since the ear doesn't respond to absolute power changes in a linear manner, and to cut this trillion to one ratio down to size, we use a logarithmic scale instead. The common logarithm of a number is the exponent or the power to which 10 must be raised in order to obtain the given number. E.g. the logarithm of 100 (10 to the second power) is 2, of 1000 is 3, and so on. Power ratios can be expressed as a logarithm, known as a Bel (after Alexander Graham), but more commonly as a deciBel, obtained by multiplying the logarithm of the power ratio by 10. This gives us a range of hearing loudness from 0 to 120 decibels, relative to the threshhold of hearing (1 picowatt per square meter), a much easier, and more useful set of numbers to bandy about. When working with your crystal set, you normally want to

$$l = n/t \qquad \text{Eq. 8}$$

We now substitute Equation 8 into Equation 2 and solve for n

$$d2*n2 - 18*d*L - 40*(n/t)*L = 0 \qquad \text{Eq. 9}$$

$$t*d2*n2 - 40*L*n - 18*d*t*L = 0 \qquad \text{Eq. 10}$$

Solving for n gives:

$$n = \frac{20*L + \mathrm{sqrt}(400*L2 + 18*t2*d3*L)}{t*d2} \qquad \text{Eq. 11}$$

Although a precise value (in inches) for the length of wire required can be calculated using trigonometry for a spiral, a very close value can be calculated as

$$w = pi*d*n \qquad \text{Eq. 12}$$

Remember that d is the sum of the coil form diameter and the diameter of the wire. This approximation assumes that the diameter of the wire is very small in comparison to that of the coil form. Also remember to allow an extra couple of inches for connecting leads at each end of the coil.

Example: A 300 uH coil is needed. The expected Q should be over 350. What coil diameters and wire sizes could possibly meet this?
Solution: Using Figure 2 it can be seen that wire sizes #12, #14, #16, #18, and #20 could achieve the required Q. Using Figure 1 the required coil form diameters are:

Optimum

Gauge	diameter
#12	7.75”
#14	6.75”
#16	3.75”
#18	3.15”
#20	2.65”

A piece of 4.5” OD PVC pipe is available and #14 electrical wire is available. From Table 1, #14 insulated wire will make about 7.7 turns per inch. Thus, the effective diameter is 4.5 plus 1/7.7 = 4.63 inches. Using Equation 11 the number of turns required is 86. Using Equation 8 the length of the winding is 11.2 inches. The length/diameter ratio is 2.4 which is a bit longer than the optimum of 0.96. The length of wire required is given by Equation 12 and is 1,251 inches. The length would have been 1,058 inches if the optimal diameter could have been used. This extra length will cause somewhat higher losses –it might still meet the desired spec though. This is about as far as I would go in rounding to an available coil form diameter.

Estimation of Inductor Q

All inductors have an equivalent series resistance loss as discussed earlier and is comprised of a number of components. We measure the quality factor or Q of the inductor by computing the ratio of inductive reactance at the frequency of interest to the series loss resistance as follows:

$$Q = \frac{XL}{Rs} \qquad \text{Eq. 13}$$

where

Q is the dimensionless “quality” factor of the inductor

---

resonant frequency of your coils. If your coil has a lot of self capacitance, it will show a dip at a lower frequency somewhere in the HF region than one that has little self capacitance. I found the oscillator particularly useful when working with short wave xtal sets. It allows you to check the tuning range of your tank circuit with enough accuracy to put you into a favorite short wave band. It really came in handy when trying to figure out the details of a shortwave antenna tuner. By coupling the dipper loosely to the tank coil of the tuner, you can check the resonant frequency of the antenna/tuner combination. It seems that with the short wave bands, your favorite xtal set antenna is actually longer than a quarter wavelength, and tuning it to a band can be somewhat tricky. The GDO helped me get the antenna to resonance.

Here is another testing gimmick courtesy of Steve Holden:

> Unless you are following somebody else's plan to the letter and using all parts that are exactly the same as he had, there will always be some "cut and try" to be done during the "breadboard" stage. Since all of my electronic test equipment combined would fit in a shoebox I use a few tricks that Pros would not use. For example if I want to find out what f range a coil and cap will tune I use a Sony shirt pocket SW (short wave) radio. I turn the tuning of the Sony to an open spot in the f range I think the LC will tune, then, with whip not extended and the radio volume set to hear noise softly, I place the LC under test near the whip and turn the varicap. If I guessed right, at some point the volume from the Sony will come up. This is because the LC circuit is functioning as a tuned loop antenna. Some more experimenting will allow me to determine what f the

Another useful piece of test equipment, also excellent for chasing dx stations, is a receiver with a digital frequency readout. My Radio Shack set, a pocket portable, fits the bill and costs about 50 bucks or so, depending on how the sales are running. It tunes in 10 kHz increments on the AM band, and I am confident the actual frequency is accurate to within a hundred Hz or less. You can use this to check the output of your sig gen, and to check its frequency; your less expensive and older signal generators have analog tuning and readout, and their calibration can be suspect. It also can be used to calibrate the dial of your crystal set in conjunction with the signal generator to at least the accuracy of a standard analog pocket superhet. You might consider this last to be gilding the lily, but having a known "dial marker " or two can keep you oriented when you're searching the dial.

A meter capable of inductance and capacitance measurements is nice to have, and I use a friend's whenever I make a new coil or want to check an unknown capacitor. Haven't seen fit to spring for one myself however. If I need to, I can always check the inductance of a new coil using a known capacitance with it in a tank circuit and the signal generator. Q meters? They're out of my league, so I depend on the kindness of strangers to tell me how to optimize coil Q.

I recently acquired a Heathkit grid dip oscillator, and found it to be a useful tool, even though its frequency range starts at 1.5 MHz. Actually, it produced harmonics, or probably parasitic oscillations into the BC band, but isn't calibrated for them; I should probably wind a plug in coil just for the BC band, but that's for another day. So what can you do with one of these? Well, you can start by using it to check for the

XL is the inductive reactance in ohms at the frequency of interest
Rs is the equivalent series resistance in ohms at the frequency of interest

Note that inductive reactance, XL, is calculated as

XL = 2*π*F*L

where
F is the frequency in Hz
L is the inductance in henries

The equivalent series resistance is the net of ohmic losses including skin effect, dielectric losses in distributed capacitance and coil structure, absorption losses by nearby conducting media, magnetic losses in nearby magnetic media, etc. With care these losses can be kept small but it takes very little loss to reduce the Q of an inductor from 400 to 200. The magnitude of Rs can be measured on sophisticated impedance equipment but it is hard to calculate the effect of all factors. Figure 2 shows an estimated value of Q at 1 MHz considering typical losses assuming the coil is wound optimally and is not disturbed by nearby lossy materials. Use the figure only as a guideline as your specific results may be better or worse. The expected Q at 540 kHz will be between about 50 to 70 percent of what is shown and the expected Q at 1.6 MHz will be around 1.2 to 1.5 times that shown.

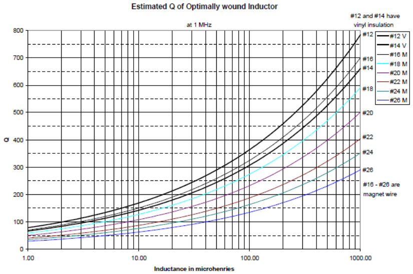

Figure 2: Estimated Q of Inductor

The Q we obtain from Equation 11 is for the unloaded coil (i.e. antenna and crystal detector not connected). The net loaded Q will typically be significantly smaller but ideally (as discussed in another chapter) would be in the general range of one hundred. Thus, we would like to start with an unloaded Q of several hundred. As can be seen in Figure 2 the Q of the inductor can be made higher by using larger diameter wire. From Figure 1 this also means using a large diameter coil form. This is a very important conclusion –high Q coils need to be physically large.

Type of wire

The only material to consider for the wire is copper. A variety of styles of copper wire is readily available. The most basic choice is between solid or stranded. Although a variety of arguments can be made for and against each, in practical terms you will not notice any difference in performance although one

---

hobby, and if I can have this much fun with a handful of cheap parts and some 20 year old, bottom of the line test equipment, working on a table set up in the laundry room, so be it. I have tried to use my "super convertible" as an rf signal generator in the regeneration mode, and it works pretty well. Just put a 2k resistor in place of the headphones, and you can used it as a nice, unmodulated signal. Yeah, it drifts some, but as long as you don't have an antenna hooked up to it, it's pretty stable. Shouldn't be to hard to couple a one transistor audio oscillator to it for some modulation. Transtronics sells their RF Signal Generator SK-303 kit for about 28 bucks. Maybe I should give it a try.

The multimeter connected across your earplug resistor also is most useful in comparing different detectors. What you are usually seeking is the best sensitivity, so first find a weak but stable station (or detune your set to make one), which gives you about 10 mV or so across the resistor (I use this value with the 47kohm resistor). Then you can readily compare different detectors by swapping them in and out of the circuit. With a digital voltmeter with readouts to the nearest 0.1 millivolts, go for a reading of about 2 mV with the station very weak but still clear. This goes faster if you use a couple of alligator clip leads for the connection. In a 10-pack of 1N34A diodes, I have found the voltage developed across the diode to vary as much as 30%; at this level, that equates to about a 2 to 3 dB difference in signal strength, even though the audible difference is small. For stronger signals, the difference in detector sensitivity is less, but doesn't matter.

Use the same setup to check out the effectiveness of your wave traps when you're cutting how the high powered stations.

the BC band, where the antenna tuner coil alone improved the signal from a 135 foot antenna by as much as 12 dB. When I put it on my Radio Shack crystal set, after first adding the obligatory 47 kohm resistor across the earphone, I found the sensitivity for it and my selective crystal set to be within a few millivolts of each other. The list of what you can do from this point is long enough to keep you busy for hours on end. One use that I also found very useful is to compare the sensitivity of different detectors; sometimes within a batch you can see differences of as much as 10 dB. On to phase 3:

For this part, you need an rf signal with some audio modulation. I happened to find an ancient but usable rf signal generator in my school lab which fit the bill. It has to be variable in frequency, and you need some way to check its output frequency, because we are going to try to measure the selectivity of your set. I put the output of the generator across the antenna coil of the selective crystal set, and adjusted the signal to a comfortable level on the voltmeter described above, about 50 mV. Then I adjusted the signal frequency up and down by 25 kHz and 50 kHz, and measured the signal output across the earphone. From a center frequency of 1100 kHz, the signal strength dropped by 12 dB at 25 kHz off, and by 20 dB at 50 kHz off. Running the same test on the Radio Shack set, the change was 2 dB and 5 dB, respectively. I don't know if my set is really any good since I haven't done much comparison testing, but compared to it, the RS kit selectivity sucks. For both rigs, selectivity improved some at lower frequencies, and was a bit worse at the top of the band. At this point, some electronic engineer type is probably reading this and shouting obscenities at his monitor for my sloppy, unsophisticated, and jerry built methods. Well, this isn't Nature magazine and I'm not trying to sell cold fusion. It's a

or the other may have physical advantages for your particular construction method. Avoid wires that are plated as those will have higher losses since skin-effect will cause most of the conduction to be in the plating which has higher resistance than copper. Avoid wires with rubber or cheap plastic insulations as dielectric losses will be higher. An exception is silver plated Teflon wire as that has the best conductivity and the lowest dielectric losses –but it is expensive.

For use in low to medium frequency inductors there is a special wire called Litzengrad or just Litz for short. It is designed to minimize skin-effect losses and is made by assembling many strands of enamel insulated magnet wire together to form a wire that has a large surface area. Litz wire is not easy to find and tends to be expensive. If you are going to use Litz wire then make sure that other losses as previously discussed are minimized. Otherwise Litz wire will make little if any difference and will be wasted effort and expense. Avoid belief in a variety of myths about skin-effect. Although it is true that skin-effect is more severe on large diameter conductors, a larger diameter still conducts better than a smaller diameter at any frequency. This can be seen in Figure 3 which shows the frequency dependence of the resistance per meter factor of some common wire sizes.

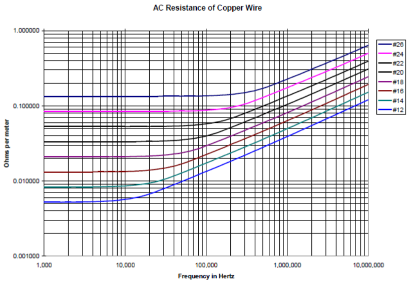

Figure 3: AC Resistance of Copper Wire

Coil Forms

From a loss standpoint air is the best coil form material there is. The obvious problem is that air has no structural strength. However, there are methods used by commercial inductor companies that employ a minimal structure so that the coil form is around 99 percent air. Manually, you can achieve the effect by first winding the coil using large diameter solid copper wire (i.e. #18, #16, #14, etc.) on a rigid coil form and then carefully sliding the winding off of the form. The stiff wire will retain the shape and you can easily space the turns to the optimal discussed previously. You will need a few supports to keep the whole thing from being too loose.

A popular coil form is some kind of cardboard tube that you have salvaged from a variety of sources such as used for paper towels or shipping tubes. These are great if you are using small diameter wire as small wire will not self support. Plastic pipe

with it? First, and obviously, you can use it to tune a station for the best signal. On a strong station, you will be amazed at how much the signal strength can vary and it not make a heck of a lot of difference in earphone volume. This is because the ear is a marvelous signal processor itself, and can accommodate a range of loudness, or signal power to the ear of 90 decibels, that's ten to the ninth power, otherwise known as a billion to one between the softest whisper it can detect and the point at which the ear starts to suffer damage with chronic exposure. Multiply that loudest sound by another thousand, you are now at a trillion to one, and the sound is so loud that it can cause physical pain. In order to handle this range of signal power, the response of the ear is logarithmic, and the power of a sound has to change by a factor of two for you to readily detect it. Since power varies as the square of voltage, this means you usually need to see a forty percent change in voltage, or about a 3 dB change in power to notice the difference in loudness. The voltmeter, being more responsive than the ear to small changes, can help you fine tune to a station, and then compare the difference in signal strengths from different stations using a number rather than an impression. Once you have played around with this a bit, it's on to phase two:

Now that you have a signal strength meter, you can start using it to optimize the settings on your rig. Using it on a receiver similar to Radio number four, which you can find on my project page, I found that the optimum tap for sensitivity and selectivity was at about 35 percent of the coil from the ground end. The 20 turn tap for the detector (for sharp tuning) showed a 9 dB loss of signal strength compared to the best tap, while giving less than a 2 dB gain in selectivity. As expected, using an antenna tuner helped, particularly in the low end of seriously load down the circuit. The digital multimeter has a virtually imperceptible effect on the signal. I tried once putting a galvanometer with a 50 uA movement in line between the detector and the earphone but the reading, which was only about 4 uA, as expected, wasn't enough to make this useful, being at the very bottom of the scale. Anyway, for my money, the high impedance voltmeter makes a much more useful tuning indicator.

If you are using magnetic headphones, which don't have the 47k resistor across them, you will not get much of an indication on the meter. Just put a 47k or some other reasonably high value resistor in series with the headphones and measure the voltage across it - yeah, the resistor cuts your signal a tad, but you're only putting it in long enough to sharpen up the rig's tuning anyway. Incidentally, there is nothing magic about the size of the resistor; I just happen to have several on hand. If you use a larger resistor, you will get a higher reading on the voltmeter, but will also have a corresponding smaller signal in your magnetic headphones. Use the smallest resistor that gives you a usable reading on the meter - this is not an absolute signal level you are measuring, but rather a tuning aid. Just to see what I could do, I tried out a cheap multimeter with a 1000 ohms/volt meter sensitivity. If I tuned in a reasonably strong station, and just put the meter in place of the 47k resistor, I could indicate enough level on the 2.5V scale, in the neighborhood of 200 mV or so, to make some use of the meter. This is pretty low on the scale, but still enough to see the effects of tuning the rig.

Okay, so now you have a tuning indicator/signal level indicator or whatever you want to call it. What can you do

is another material you might consider. None of these materials are made with any consideration about high frequency dielectric losses but because only a small amount of material is used the losses are probably minimal.

Wood is a convenient coil form and has low losses if very dry. Common sizes that have been used are 2x2, 4x4, or a pair of 2x4 combined to make 4x4. Round dowel rods may also be used but their diameters are often much less than optimum. When using a square coil form there is a logical question about how that affects the inductance calculations. A simplistic (but good) answer is to use an effective circle diameter that has the same area as the square form since area is a strong factor in inductance. Losses with a square form will be somewhat higher than for a circular form. Rectangular forms (such as a single 2x4) have even higher losses in comparison –it takes more wire to encompass a given area.

Winding the coil

Counting turns is a tedious and error prone task. It is much simpler to cut the length of wire needed and then wind that until finished. The resulting turns count will be very close if not exact. Wire is springy and will jump off the form in a tangled mess if not restrained. Start by securing the wire at one end of the form and have a means for easily (preferably with one hand) securing the opposite end when you finish. It is tempting to use some kind of adhesive tape and that will work if you are careful and understand what you are doing. The forces will build and the tape may give way which will result in a frustrating mess of tangled wire. Make sure the tape can not slip. A good way to secure the ends is to first drill a hole in the tube at the starting and end points. Then feed the starting end through the starting hole and bend the wire such that it naturally resists tension and secure the wire with tape. Stuff the loose end length inside the tube so it is out of the way while winding.

It is best to wind the coil by hand as the set up for using a lathe is not worth the trouble for a single coil. There are a number of “poor man’s” lathes such as a power drill that have been used but I do not recommend that as you are more likely to make a mess or cause injury than you are to wind a coil. It only takes a couple of minutes to wind a coil by hand so take the time to think what you are doing. It is important to keep the winding tight at all times. The wire will spring off if it ever gets loose. You will very likely have some fractional turn as a result of your calculations. I recommend that you round that to the nearest integer as it is not worth the trouble of making measurements to stop at a specific fractional turn.

TESTING YOUR CRYSTAL SET

(22 Nov 01)
Owen Poole
http://bellsouthpwp2.net/w/u/wuggy/testing.htm

If you like to fiddle around with your crystal sets, then you need some way to do comparisons of before and after when you want to try something new. If course, the obvious is to listen. If it sounds louder, it is. If you don't hear the other station that is close in frequency any more, then selectivity is better. If you hear everything you want, then your set is working fine, and you need go no further. If you are trying to push it a bit, however, some reasonably objective yet quantitative measurements are helpful for you to optimize your set and to compare the performance of different sets, antennas, modifications, etc. Here are a couple of things I do with my rigs:

Get a DC voltmeter which will measure small voltages in the millivolt range. I use either a digital multimeter or a RS analog multimeter with about 20 thousand ohms per volt sensitivity (less sensitive meters will load down the circuit unacceptably, and will probably not measure down in the millivolt range, but go ahead and try if you have to). The RS analog model I have has a 0.6 VDC (600 millivolts) scale which works pretty well. I then connect the meter across the 47 kohm resistor which is also across the crystal earphone. Using this setup, my closest local BC station, less than a kw about 6 miles away, gives me a reading of about 190 millivolts. A station with a 50 kw daytime signal about 75 miles distant comes in at about 30 mV. With the analog meter, there is a little insertion loss, about 10 mV, but not enough to

ANTENNA MATCHING

by Kenneth A. Kuhn
http://www.kennethkuhn.com/students/crystal_radios/antenna_matching.pdf

As discussed in an earlier chapter the ten to thirty meter antenna used for crystal radios has a very low resistance and a high capacitive reactance. The ground resistance discussed previously is typically in the several tens of ohms and is effectively in series with the antenna. As an example, an antenna/ground system may have an impedance of 20 –j1000 ohms at 1 MHz. For maximum power transfer from the antenna to the resonant circuit the input impedance of the set should be a conjugate match –that is have similar resistance but the reactance will be equal in magnitude but opposite in sign. For the example this means that the crystal set should have an input resistance of about 20 ohms and a reactance of about +j1000 ohms (160 uH) at 1 MHz. The positive reactance is obtained by an inductance in series with the antenna circuit. This inductance should be variable to tune out the capacitive reactance of the antenna across the AM broadcast band. Tuning is not sharp as the Q of resonance is low. Table 1 shows some typical values. Note that the inductance tuning range becomes wider for longer antennas since the capacitive reactance drops rapidly as the length approaches one-quarter wavelength at the upper end of the AM band. It is important that this series inductance have very low losses or the advantage of using it will vanish –a lossy inductor could be worse than nothing.

Antenna Length	**Typical Antenna XC @ 550 kHz**	**Typical Antenna XC @ 1.7 MHz**	**Antenna series Inductor tuning range**
10 m -	j4040 ohms -	j1250 ohms	1200 –120 uH
15 -	j2680 -	j780	780 – 70
20 -	j1990 -	j530	580 – 50
25 -	j1580 -	j360	460 – 30
30 -	j1290 -	j240	370 – 20

Table 1: Antenna series inductance tuning range

One effect of not tuning out the reactance of the antenna is that the resonant frequency of the tuned circuit will shift because the antenna becomes a reactive load. One way to know if the series inductance has been tuned to the right value is that the station is received at the calibration point –assuming the radio tuning was calibrated.

The next issue is creating a low input impedance of several tens of ohms. There are two ways to do this and they are essentially the same. One method is wind a turn or so of wire near the ground end of the coil of resonant circuit –one end of the wire goes to the series inductor to the antenna and the other end connects to ground. This small winding transforms the low antenna/ground impedance to a high impedance across the coil. The other method is to make a tap a turn or so above the ground end of the coil of the resonant circuit to accomplish the same effect. If the winding or tap is too few turns then there is an impedance mismatch and a weak signal will result although selectivity will be relatively sharp. If the winding or tap has too many turns then the coil is overloaded by the antenna/ground impedance which also results in weak signals and the selectivity will be broad. The optimum is the point of

All variable capacitors have vernier drive dials.

proper impedance match although it is not very critical. The issue is how to determine the proper point. A second issue is that the required impedance level varies across the AM broadcast band. Thus, the tap should be variable.

If the coil is wound on a ferrite toroid core which enables a high degree of flux coupling from turn to turn then it is fairly easy to calculate at what turn a tap should be for the desired impedance transformation. However, our coil is typically an air-core solenoid which has a complicated flux relationship. Calculation is difficult and very error prone. The best way is to make a variety of taps and measure the impedance using laboratory methods and note the results. I will present the data of just such an experiment on a typical coil for crystal radios when this article continues …

took out the tree at the other end. The shorter flat top worked so well I brought it here to Hawaii, where real estate for long antennas is at a premium. It's about all I can fit gracefully onto this lot. Ground is tapped directly into the city water system.

Circuit Details

The antenna-ground system is tuned by the primary, L1-C1, and is coupled to the secondary, L2-C2, via loose L1 - L2 coupling (physical distance 3 to 4"). L1 and L2 are positioned radially (side-to-side), while the coils of two QRM traps (high-Q, parallel L-C ckts.) are coupled axially to L2. L1 has virtually no effect on L2-C2 tuning and Q, but the QRM traps do affect tuning, especially near the QRM frequencies. So, their coupling is kept to the minimum which will still allow reception of the stations of interest. The set is capable of receiving stations on frequencies adjacent to murderous locals. The low-Z sound-powered phones are impedance-matched to the secondary tank , L2-C2, and detector with a UTC A-27 100 k-ohm-to-200 ohm input transformer. The single12101 diode detector is estimated to present about 200 k-ohm resistance in the forward direction. These impedances, in series, allow you to place the detector-phones directly across the tuned circuit without undue loading. Taps, used in the past, are a mess -- especially with litz wire. Further, they kill a coil's Q, and are to be avoided if at all possible.

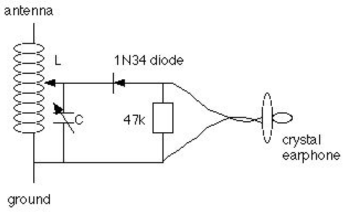
VARIATIONS ON A SLIDER-TUNED SET

Owen Poole

http://bellsouthpwp2.net/w/u/wuggy/slider.htm

My first crystal set used a prewound coil, a slider for tuning, a catwhisker and galena crystal, and had a large square mica capacitor (remember those?) across the headphone terminals, feeding a single 1000 ohm headphone. For a variety of reasons, which I don't remember 40 plus years later, it only got one or two stations in Atlanta, GA, but, even at that, it was still magic. Back in an era when responsible parents believed children should remain at least one economic level below their parents, having a radio of any type in my room was doing pretty well, and life was good. This type of set is tricky to use, since maintaining contact between the coil and the slider is touchy, and then you have to find a good spot on the galena crystal with the catwhisker, also easily knocked out of adjustment. Still, it has its advantages; it's inexpensive and it works. The headphone was a cost driver, and throwing in a variable capacitor could easily double the cost. A step up on the ladder came when AM tuning coils with slug-tuned ferrite cores came on the market, which were used in the tank circuit with a fixed capacitor, and feeding a germanium diode. I had a "pocket" receiver which had these as well as a pretty sensitive earphone which was built into the case.

About a year and a half ago I had a nostalgia fit and built another slider, but used a crystal earplug, a 1N34, and even added a 365 pF variable capacitor, remembering the tricky slide contact problem, but wanting to be able to vary the L/C ratio over a range of frequencies. The set worked pretty well, but lacked selectivity. This is a drawing of the set:



I found that the best place to connect the antenna and ground depended on the antenna used and probably on local conditions. Sometimes connecting the antenna to the slider worked well. I tried the detector tap at the top of the coil, as some designs do, but selectivity really suffered. Some selectivity improvement was seen when I wound a smaller coil for an antenna loading coil and put it up inside the tuning coil. Again, you can still play with where the antenna and ground are connected; you can put the antenna or ground to the loading coil, and try the other on either end of the tuning coil or on the detector connection. You can also make your earth ground to both the loading coil and the tuning coil. The best arrangement is what works best for you. An operating benefit of connecting the detector to the slider is that you don't hear anything unless the slider is making contact with the coil.

(3) if necessary, pad the variable capacitors with high-quality air trimmers to get to lowest frequency and spread out top-end tuning

(4) choose coil design which peaks in Q in the central BCB range -- operating near the self-resonant frequency is self-defeating

Superior quality tuning capacitors (silver plated with ceramic standoffs) were used in the present version. The two prime tuning capacitor candidates I had were a 500 pF and a dual, 470 pF per gang, both silver-plate, ceramic insulated. (Typical parallel leakage resistance measurements on these were 20 megohms, by the Boonton 260-A.) Accordingly, the set was designed about them.

I credit Bill Bowers of Oklahoma with exposing me to the virtues of finer-strand litz for medium frequencies, the use of larger coil diameter-to-length ratios (ca. 5-to-1) than theory suggests, and for going back to 'over-1, under-1' winding pattern. They are not as pretty and have lower L's than the same-sized 'over-2, under-1's', which I used for many years, but they do have substantially higher Q's.

And credit to Al Klase for preaching the virtues of sound-powered phones long enough and loud enough that I finally had to listen -- despite my being firmly convinced nothing could ever surpass Brush crystal phones. The sound-powered's are a real ear-opener, literally, and an order-of-magnitude improvement.

Antenna has been, for some time, a 50-foot, 4-wire flat top (wires spaced 1 ft. apart), maybe 25 feet high. At my previous location, I used to have a 105-ft. long-wire, but high winds

Summary

The "Lyonodyne-17" is a much-advanced version in a series of DX crystal sets evolving from circa 1974. I've been particularly interested in crystal sets since 1959, when I first discovered you could actually DX with them. It's a completely passive set -- no amps, no bias on the detector. The circuit is double-tuned and uses super-high quality components: silver-plated variable capacitors and high-Q litz wire basket-wound coils. Isolated coil Qs are in the 700s across the BCB and over 1000 for much of the BCB. In-set Qs are less, of course. Phones are high quality, surplus sound powered ("balanced armature") units, matched to the high-Z secondary tank/detector by a high quality line transformer. Detector is a single 12101 3RT, sold by Radio Shack as a "1N34 Type." It's the best I've found so far. With traps and all, it takes up the better part of a desk top.

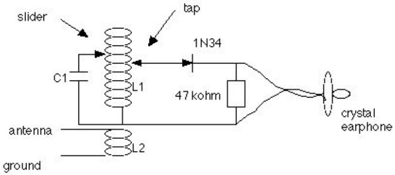
Description

After several abject experimental failures, I concluded that the magical "high L-to-C ratio" for tuned circuits is a crock -- in spite of what theory might suggest. That, and the high Qs obtained in 200/44 litz wire (now, 660/46) coils got me to re-thinking my set's design and construction. This led to a completely rebuilt crystal set -- same circuit, but redesigned components per the following principles:

(1) design for the lowest L/C ratio as practical

(2) use highest quality variable capacitors available

My latest design attempt, which shows promise in the breadboard stage, goes back to a fixed capacitor in the tank circuit , but incorporates an antenna loading coil and separate detector taps, two features which I consider essential to selectivity in a single tuned set. The drawing for this rig is shown below:



My coil was 100 turns of #26 magnet wire close-wound on a toilet paper core, with detector taps at 10, 20, and 30 turns from the bottom (connected) end. The antenna coil, L2, is 15 turns of #26, also on a tp core. I chose to separate the coils so I could move the antenna coil about to vary coupling, but could probably have done about as well winding both coils on the same core with about a 1/8 to 1/4 inch separation between them. Note: I found that the loading coil had to be placed at the bottom end of L1 as shown; placing it at the open end didn't work very well at all (for me). For a slider, I just straightened out a large paper clip, soldered it with a stranded hookup wire into a soldering lug, and then used a wood screw to hold the slider to the base I used. Just for grins I rolled my own fixed capacitor, C1, making it about 300pF.

On the air results were pretty good. The detector tap is selected by an alligator clip. I got the separation I wanted between the two strong locals that are 50 kHz apart, sensitivity is ok, BUT, the rig design still needs some work before I offer it to my students. Current problems and possible solutions: a). Only using about half the coil, and it tunes pretty fast - use larger wire, maybe a smaller diameter coil form, and maybe a smaller value capacitor. (probably do at least two of the three)

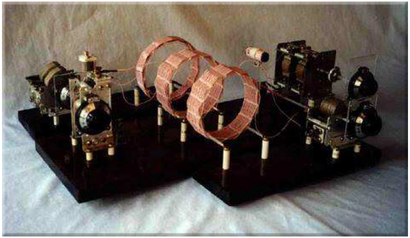
b). Not happy with the paper clip slider; too flexible so you get backlash, and doesn't ride smoothly - use a metal strip and maybe add another washer where it connects to the base.

c). With detector tapped directly to the coil, you always hear something, whether or not the slider is making contact. I guess I can live with this.

Lyonodyne Version 17 Crystal Set

from Mike Tuggle

http://www.crystalradio.net/crystalsets/lyonodyne/index.shtml



Builder and Operator Mike Tuggle

The "Lyonodyne-17" is an advanced DX crystal set evolving over the years. It was a first place winner of the DX "Open Class"contest two years in a row in 2000 and 2001. Mike placed second in 2003 after handicapping himself by using a rock (lead telluride) as the detectors. The radio incorporates the "Tuggle" front end (which will be shown later), and very high quality parts.

Note:

This is not intended as a "How To" article for a beginner. The following is supplied as information only. Some of the techniques used in the construction of this radio are very advanced and not recommended for a beginner or even an intermediate builder.

My own experiences over the years have led me to shed my skepticism of the incredible DX reports made by old-timers back in the early days. Component technology was not what it is today, but circuit technology was, and the sparsely populated bands back then had to be a lot more DX-friendly. You may want to pull an antique crystal set off the shelf and give it a spin. I'd encourage it.

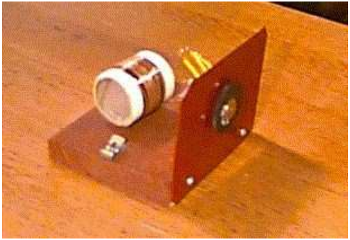
Some of these old sets are extremely well built. The construction of the military BC-14A/SCR-65 never ceases to amaze me--and others were built just as well. But to start out, I'd recommend conceding to modern technology by using a good, modern diode and sound-powered phones with matching transformer. With just a little luck, prepare to be amazed all over again!

A CRYSTAL RADIO WAVE TRAP

Owen Poole

http://bellsouthpwp2.net/w/u/wuggy/traps.htm

This is a little circuit that is a real giant killer when you are trying to nose up to a loud local to look for the little guys. Basically, it is a tuned circuit placed in the antenna path to your rig, which traps and then dissipates the signal, or at least a bunch of it, from a station, allowing you to reduce interference between stations. There is nothing fancy to it, but a little care in construction and operation can make it really work well. Here is one of mine:



I used a 1 1/4 inch diameter cardboard core, and wrapped 100 turns of #32 enameled wire around it, closely spaced, and attached the ends of the coil to a 200 pF variable capacitor. This forms the tank circuit. I also wound over the first coil a second one, using 15 turns of #22 enameled wire, and ran each end to fahnstock clips - the antenna is connected to one clip, and the second goes to the antenna tuner, the set, or what have you. To use, just tune your receiver to the offending station, and then adjust the trap's capacitor until it reduces the signal. About 15 seconds is all the time you need to become a pro. The #32 wire, being of relatively high resistance, dissipates the signal that makes the tank circuit resonate (real engineers have assured me this is a bunch of baloney, and they are probably right, but my little trap works fine for all that - smart money says to make it of larger wire). . The #22 wire transfers the signal inductively from the antenna circuit while offering a low resistance path for other frequencies. It tunes fairly sharply, so tune slowly. You could install a bypass switch for times when the trap isn't needed, but I just tune to trap out of the way, with no signal loss to that I can notice. If you have more than one station you want to knock out at the same time, put more traps in series with this one. I have two which I use to cut out the two strong signals from two stations dominating the top of the band only 50 kHz apart. They are still too close together to listen between them, but I can certainly get much closer above and below them now. I might try a few more turns on the smaller coil to see if it sharpens up the signal a little. This was a first attempt, and I haven't tried to optimize it. Had I wound the coil for about 400 uH, I could have gotten full band coverage - actually, in my QTH, there are no loud ones below about 690 kHz, so this setup works fine for me with the 200 pF capacitor.

While you are winding the 100 turn coil, go ahead and put a tap in it, say at 30 turns or so. Then you can use the trap for a crystal set as well by adding a detector and earphones across the 30 turns. This lets you do at least two things: 1. It is a nice little crystal set all by itself. 2. You can operate it as a

closest some 2400 miles away? As it turns out, Hawaii is an ideal DX location--for distance if not for sheer numbers of stations. With no regional stations, sunrise-sunset activity is non-existent.

West coast 500-watt stations, 2500 miles distant, have been heard here. High-power stations in Cuba (4800 mi.) and the Caicos Islands (5500 mi.) have also been heard, thanks to a mostly water path. Stations from the "interior" also make it over. Last year, it was neat to hear KRVN in snowbound Nebraska (3600 mi.) using a homemade cat's whisker mineral detector. This must be what it was like in the old days.

With low station powers and crowding, medium-wave broadcast band DXing represents the greatest challenge. On short wave there's no limit to the distance--reception is truly worldwide. I occasionally hear the South African broadcasts nearly 12,000 miles away; Johannesburg and Hawaii are nearly at antipodes. From the mainland, Australia (11,000 miles) was a routine catch. Figures 5 and 6 show my "12,000-mile" crystal set.

Crystal Set DX Activities

Crystal set DX activities include discussion forums sharing ideas and results, an annual DX listening contest now into its sixth year, and the occasional set-building contest where some remarkably high-caliber craftsmanship comes to the fore. All of these activities are served up on the Internet.

The following site is a highly recommended grand portal to the wonderful world of crystal set DXing: Owen Pool's Crystal Radio Resources at http://www.thebest.net/wuggy. The comprehensive set of links here covers all aspects of the hobby. This site is headquarters for the annual crystal set DX (XSDX) contests open to everyone. The contest usually takes place in late January. Watch for announcement of specific dates and rules.

antenna. The rule of thumb is, if you can hear them on a radio, you can hear them on a crystal set.

The best times to listen are at sunrise and sunset, when stations are signing on or off, raising or dropping their powers, and changing their antenna patterns. These circumstances make for a jumble of regional stations ripe for the picking. Deep night is usually the best time for flat-out DX.

In 15-year stints at two locations in Maryland, I accumulated logs of over 600 and 400 stations, respectively. The most distant receptions, at 1800 to 2200 miles, were a few powerful stations in the Caribbean area and adjacent South America. I was aided, no doubt, by the largely water path between them and me. The farthest overland station was in Denver at about 1500 miles.

When I moved to Hawaii, I wasn't sure what to expect. The local Honolulu stations were givens. But what about the outer islands? And all-importantly the next stations, mainlanders, the

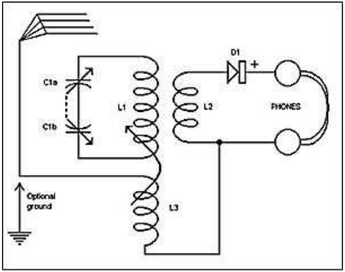


Fig. 6. Schematic of the '12,000 mile-er.'

---

crystal set alone, listen to it while you adjust the trimmers on the capacitor for best frequency coverage - particularly handy if you use a different size wire, different number of turns, different capacitor or different diameter core. Don't leave out the smaller coil of #22, or whatever you use; I tried this trap without the small coil, and it literally wiped out the whole BC band, no matter what frequency it was tuned to - on the other hand, if this is built to be resonant at the shortwave broadcast freqs, it cuts out a larger portion of the offending band.

More fun; put it in the ground path instead, and it works about the same. Put it before or after the antenna tuner (if you use one) - works about the same. Use it as a crystal set along with the other set, and you can listen to two stations at the same time - no, you can't listen to the same station with both sets if they are in series - the one rig cuts out the other. You can even use a trap to provide power to a small transistor amplifier stage if the trapped signal is large enough.

On the air testing with a dc millivoltmeter across the 47k resistor in my detector circuit (see my testing page) shows a signal reduction on "trapped" stationsof about 6 to 14 dB with the trap. I suppose if you have a real monster in your neighborhood, you can put two traps on it for a double stomp;
I couldn't see much advantage to the second trap when I tried this. I have not found the need to use a trap bypass switch when the trap isn't in use; I just shove the tuning cap to the other end of the band, and don't notice a reduction in set sensitivity elsewhere. I also notice that on really strong locals, the difference in signal level of 6 dB or so isn't very noticeable, and tuning the trap "by ear" is a bit difficult. When I tune off the offending station a bit, however, I can see the

effect of the trap more readily. I made mine as an outboard unit, but you can just as easily incorporate into your main set, just don't make the coils of the two circuits in line (on the same long axis) with each other or you will mutually couple them, which makes for confusing tuning.

One of the unexpected benefits of a trap, as I found out, is that it can enhance the operation of an otherwise sensitive but not so selective crystal set. Using a trap with slightly modified Radio Shack crystal set, I heard a brand new station coming in from several hundred miles away that was ordinarily masked by a stronger station.

Trapping with the pros: Probably the most effective trap is an inductively coupled one. Here's how to make and use it: Make a coil of the same dimensions as your set's main tuning coil, and parallel it with a variable capacitor, also like the one your set uses. Now, place the new trap coil in line (on the same axis) with the main tuning coil, and, with the set tuned to an offending station, tune the trap capacitor to null the station. You can vary the depth of the null by moving the two coils apart. If your set has a separate antenna tuning circuit, the trap coil should be on the side of the set tuning coil away from the antenna coil. I have one of these and have gotten over 30 dB of fairly sharp signal rejection with it. Be advised; when using an inductively coupled trap, expect some interaction with the tuning coil. Using an inductive trap can give some interesting results you don't get from one placed in the antenna line.

More trap fun: If you have a set using in-line antenna and main tuning coils, inductively coupled to each other, here is

These phones are low impedance and must be matched to the high-impedance tank (L2-C2) and detector diode by an audio transformer having, typically, 50- to 600-ohm and 50- or 100-kilohm windings (Figure 4). The quality of the transformer is very important, so that its insertion loss is small. UTC input transformers have a good reputation for low loss. The final touch is a comfortable set of headphone cushions for good acoustical coupling to the ears and exclusion of outside noise.

DX Experiences

Under favorable conditions, medium wave or broadcast band

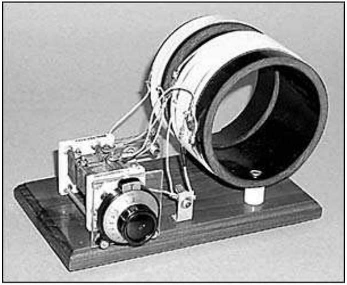

Fig. 5. A '12,000-mile' short-wave receiver.

DX crystal sets can receive hundreds of stations--some of them thousands of miles distant. In fact, DX crystal set performance is comparable to any other radio (powered or not) short of a full-blown communications receiver with its own outside capability to put up one of these 'mega' antennas. So it behooves us to heed principles 1 and 2.

The front-end (antenna tuner) design shown here is one of several that can be used. This particular design tunes a wide variety of antenna-ground systems. Other DX crystal sets use a simple series tuning circuit effectively--especially on long antennas.

The diode detector provokes more mystery, controversy and debate than any other component. Some folks favor low-resistance germanium diodes like the 1N34A or rock stands with galenas. Others swear by high-tech Schottky diodes. The emerging truth is, there is no universally perfect diode.

The 'best' diode depends specifically upon the set it is used in. Per the second principle, the diode needs to match the tank circuit feeding it and the transformer and phones that it feeds. With some care, a high-Q tank with litz wire coil and a modern, military-grade variable capacitor can attain a resistance of from several hundred kilohms up to a megohm. Only Schottky diodes and a few modern germanium diodes have resistances this high. The old catswhisker-rock stand detectors have far lower resistances.

The most practical approach to selecting the right diode is to apply an A-B listening test to a number of them. Two diodes are mounted in a test stand arranged to quickly switch between them. Using a fairly weak station, one can test a pile of diodes, pair-wise, keeping the winner after each test, until the ultimate one is found. But it's most important to realize that this diode is 'best' for the particular set it was tested in. It may be a quite poor performer in a different set.

Surplus, sound-powered (more properly, balanced-armature) phones have become the industry standard for DX crystal sets. Baldwin Type C's were an early example. Now, post-WWII surplus units made by RCA and US Instruments Corp. (USI) are preferred.

something else to do with your inductively coupled trap. When trying to dig out a weak station, get as close to it as you can, then tune the trap for a null. Now, take the trap coil and place it between the antenna and main tuning coils. With some careful tuning, you can often isolate the weak station. The trap is giving you an additional stage of filtering and selectivity, and you are now using "triple" tuning. In this configuration, the trap is now functioning as a transfer circuit. You will notice that best performance is with the coils separated from each other by a coil diameter or so.

Larry Pizzella also reports good results with in-line traps using largish coils, with the tuned circuit portion of the trap inductively coupled to a separate coil connected to the antenna line which can be moved away from the main trap coil to provide variable coupling. If you look at his big radio, you can see a couple of his outboard traps as well as his inductively coupled trap (the large blue coil on the far right).

I would like to report that trapping my two strong locals opened up the top of the band for me; it didn't completely, but I can now get stations as close as about 20 kHz.

I have been able to successfully trap the HF ghosts somewhat that bedevil me early in the evening, but feel the need to work on this some more. Multiple hf intruders are really tough, but the hf trap I made doesn't use a coupling coil, and is rather broad, so gets a largish portion of the lowest shortwave broadcast band, and supresses a couple of stations sometimes.

We have, from left to right: antenna-ground system, front-end (antenna) tuner, secondary (detector) tuner, diode detector, audio matching and finally, phones. Maximum transfer of available signal power from one stage to the next happens when the impedances of these stages are matched to each other--from antenna to phones--and indeed, from phones to one's ears.

Components

A good outside antenna-ground system is essential for DXing. Loop antennas do not have enough pickup to be effective. An inverted L longwire 20 to 30 feet high and 50 feet long is a good start. The one truth to antenna design is, "higher is better." Any effort expended to raise the antenna, even a few feet, will be amply rewarded. In the most recent crystal set DX contest a third design principle emerged: A huge antenna can overcome shortcomings in the first two principles.

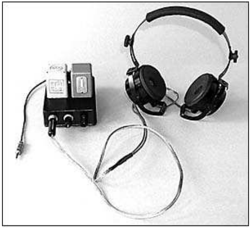

Fig. 4. RCA balanced-armature phones, with matching transformer.

The winner suspended 140 feet of litz wire near vertically using helium-filled balloons. Another high-scorer just happened to have a 140-foot tall base-insulated tower and four 1000-foot Beverage antennas to complement his junk box set. Most of us have neither the real estate nor the rigging

Design Principles

Two fundamental principles underlie DX crystal set design and construction: use of low-loss components and proper impedance matching between stages.

Avoid the temptation to construct the set with vintage components. The result may be a handsome set that is only a fair performer. I have such sets, and they sit up on the shelf and look nice. However, for ultimate performance, one should rely on top quality (usually modern) components and materials.

This is especially important for tuning capacitors, coil wire and forms, and detector diodes. Layout and construction, particularly in the RF-carrying sections (antenna through detector), should follow good HF practices: short direct leads, careful insulation of components, and avoidance of switches, taps and other trappings in the 'hot', RF-carrying sections.

The crystal set, like any other radio, consists of a series of stages--each with a function, each coupled to the next. The stages of a simplified crystal receiver are diagrammed in Figure 3. The resistances shown are used for detailed circuit analysis that will not discussed here.

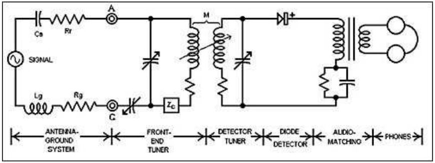

Fig. 3. The stages of a typical DX crystal set (see text).

BANDSPREADING TECHNIQUES

(20 June 99)

Owen Poole

http://bellsouthpwp2.net/w/u/wuggy/spread.htm

Bandspread in a crystal set? You must be nuts! Well, maybe so, but let's give it a shot anyway. Bandspreading is nothing more than making it possible for you to tune your set more slowly. Why bother? Well, if you are in a crowded band, such as in a metropolitan area with lots of strong stations, you have probably already gone for more sophisticated crystal radio designs to allow you to separate the signals. Even in my location, with two peanut whistles only 50 kHz apart, sometimes I still have to tune very carefully when my rig is set up to be selective so that I can get the station I want, and not hear the other. In the HF (shortwave) region, with stations fading out and then roaring back with regularity, being able to tune slowly allows me to catch stations that are just out of the mud, but are more often buried by the stronger stations that usually dominate, and which catch my attention easily. With HF ham rigs, the ability to tune slowly is an absolute necessity; otherwise you sweep right past stations that are only in your selectivity skirt for a few hundred Hz. Most crystal sets use a tuning capacitor that has only a180 degree rotation in going from around 10 to 360 pF or so - on the BC band, this gets you through the 1.2 MHz-wide band rather quickly - on HF, you cover several MHz, and a quick sweep through the frequencies can cause you to miss stations if you are only expecting what you normally hear.

There are two basic types of bandspreading: Mechanical and Electrical

Mechanical: The simplest way to slow your rate of tuning down, or at least let you tune more sharply, is to use a larger tuning knob; your ability to control your tuning rate varies directly with the diameter of the knob, assuming you grab it on the outside edge. Another method that used to be popular was to have a small diameter shaft turning a larger diameter one connected to it by a dial cord; the cord was usually kept tight by a small spring. A third way, still much in use, is to have a planetary dial drive which makes several rotations to drive the capacitor through one half a rotation. Dial cord drives are tricky, and planetary drives can cost more than the rest of the set, so I usually go for the largest knob I can find. Another thing to watch out for with mechanical bandspread drives, should you try one, is backlash or slop - you reverse your direction, and lose a couple of degrees of turn before the capacitor starts to move. For inductive tuning, usually consisting of moving a ferrite core in and out of the coil, the once readily available AM tuning coils used to come with a metal cap through which a screw protruded that allowed you to vary inductance very slowly using a small knob to twist the core in an out. Compression capacitors also use a screw to let you make several turns from stop to stop, but aren't ordinarily used for main tuning, and are usually for screwdriver use only. If you do stick a knob on a compression cap with some epoxy, a soda bottle cap should work, and will allow you about 3 or more revolutions of rotation stop to stop.

Electrical: Nothing magic about this either. Here you use two or more capacitors to change the amount of capacitance a turn of the knob gives you. Shown below are some of the more common ways to electrically bandspread your tank circuit:

So, what makes a crystal radio a "DX" set? Well, this one is double-tuned (L1-C1 and L2-C2) for selectivity to tune weak DX stations in the RF jungle we now live in. Some DX sets resort to triple tuning for even more selectivity -- depends on how many hands you have to do the tuning. The wavetraps (L3-C3 and L4-C4) can be tuned to reject strong unwanted stations in the manner of the notch filter on a communications receiver.

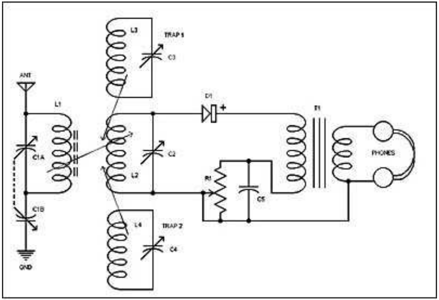

Fig. 2. Schematic of the 'Lyonodyne-17.'

Coils L2 through L4 are basket-wound litz wire for low loss and high Q. Variable capacitors C1 through C4 are highest-quality, silver-plated, ceramic-insulated units--as perhaps only the military could specify. All these components are isolated from the mounting board by ceramic standoff insulators. Overkill maybe, but why take chances?

particularly interested in crystal sets since 1959, when I first discovered you could actually DX with them.

The Internet has aided crystal set DX activity by making exchange of ideas between like-minded enthusiasts much, much easier. This article only touches the surface from a personal perspective. The reader is encouraged to pursue the online resources, described below, covering all aspects and providing further examples of this fascinating hobby.

In this article I'll cover general design considerations for building DX crystal sets, but will leave the actual construction specifications up to you.

Equipment

Figures 1 and 2 show an example of a DX crystal set. I call it the "Lyonodyne-17." The design evolved from an earlier version described in the November, 1978 OTB. As you can see, this is not your grandfather's crystal set.

Antenna (right) and detector (left) tuners are mounted on the middle board. Wave traps are located fore and aft on separate boards, making it possible to adjust the coupling by moving the boards. The antenna coil (L1) is wound on a short ferrite rod. The matching transformer unit for my RCA "Big Cans" sound powered phones is at front, left.

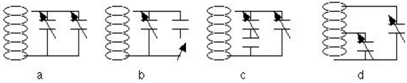

Figure a. is one of the favorites. If one capacitor is significantly larger than the other, it is called the band set capacitor, and the smaller one is the bandspread capacitor. Capacitor size ratios of from 2:1 up to 10:1 should be used. Keep in mind with all of these that minimum circuit capacitance is the sum of the minimum of both capacitors. Since the polyfilm caps I usually use, because they are cheap, only run to about 200 pF, I sometimes just put 2 in parallel to get full AM band coverage (and 360 degrees of rotation at the same time). Incidentally, since these capacitors are really two sections, a 150 pF and 50 pF, you can get full band coverage with a 200 pF capacitor, with both sections tied together, and only the 150 pF section on the other; use the 150 pF section for the top part of the band and it will slow your tuning rate down a bit.

Figure b. is sort of a poor man's bandspread, switching in one or more fixed capacitors to increase capacitance in increments, then adjusting the variable as needed. I used this with my peanut special to get to the bottom of band. The fixed capacitor should be no larger than the range of the variable to prevent skipping over frequencies.

Figure c. has a fixed capacitor in series with one of the variables. This reduces the tuning range of the series variable from about the minimum of the variable to the value of the larger capacitor in the series branch. Good to use if you don't have any small value variables.

Figure d. taps one variable down on the coil, reducing its effect on tuning range. In this case, assuming it is the same value as the band set capacitor for example, its effect capacitance-wise over its full range is approximately equal to the percent of the coil it parallels. If you use a switch to select different coil taps, you can thus vary your bandspread.

A note on using fixed capacitors: I have found that some are better than others, and a lossy one can reduce set sensitivity when the fixed cap is switched in. I have seen this with the readily available ceramic disc capacitors. This may not happen to you, but just be aware of the possibility. You might want to try different types here. Try to use good quality switches as well, and make good solder connections....

Finally, to use the K.I.S.S. principle, use a capacitor with a range no bigger than you need. That is, use only enough range to cover that part of the spectrum in which you are interested. Using a single 365 pF capacitor on the HF bands, one turn of the dial will sweep through several MHz, and no matter how selective your crystal set, you will be sweeping through a lot of dead frequencies and then sweat tuning in and then separating the stations you want to hear.

You can pretty much do with inductors (coils), what you can do with capacitors, and some of the old designs used a lot of variable inductances. Putting inductors in parallel has the

same effect as putting capacitors in series, and vice versa for series inductors. My uncle Elmer (I must have had one sometime) told me, however, that circuit Q was highest when you used as much inductance as your frequency range allowed, and to let the capacitor do all the "heavy lifting". Still, some of those old variable inductors look pretty elegant, and I am sure they work pretty well, even if they are a bit more complex to build.

switching the absolute phasing, don't worry about it. Many cannot and it's one less thing for you to concern yourself.
Position 1 on SW1 permits use of an efficient 4, 8, or 16^ speaker on very loud signals, or use of headsets with very low impedance ratings similar to those speakers.

Output Using Input2/Output Combo
The 'High' side terminal of input 2 may be used as the 'return' for the headset for the xtal detector function if it is desired to select a winding ratio 'inside' the normal selections. Connect the headset to the 'high' side output terminal (from SW3) and it's other lead to the 'high' side of input 2. SW1 is then used to select a tap for the 'low' side of the headset connection, SW2 selects the 'high' side as before. This 'inside' option excludes selection/use of the position '1' 8^ speaker tap.Some headsets will match up better using this option.

Absolute phasing may then be reversed/corrected by reversing the switching order of SW1 and SW2 , thus reversing the 'high' and 'low' sides of the headphone conections without need to disconnect and swap them, once the best ratio selection is found by ear. Correct "Absolute phase" refers to the the condition where a pressure 'push' into the studio mic gives a pressure 'push' from the speaker or headphone. Absolute phase reversal results in an unnatural result of a 'push' giving a 'pull'. Some listeners find clearer & more lifelike voice sounds when absolute phasing is correct.

Steve Bringhurst

Parts List
(UltiMatch and UltiMatch 2)

to the headphone being used. The position giving the loudest & clearest sound is usually the best setting. SW3 is used to select bass response balance for the headset and input device in use, the 1st position is 'direct'. This adjustment will have a more subtle effect than a regular tone control.

Input 2
Input 2 is used for powered devices like tube & transistor detectors & amplifier ckts with SW4 in the 'low' position. SW1 is used to select the proper input match for the powered device. Always start from the highest setting first when using this function, too low a setting may damage the powered device. Using SW2 selects the best match for the headset as before, or position 1 can drive a loudspeaker directly. The loudest & clearest sound is usually obtained when SW1 & SW2 are optimum.

Output
Any set of headphones or single earpiece, such as a telephone earpiece, may be connected to the 'output' terminals. It is usually preferable to have 2 earpieces connected in series, rather than parallel, & properly phased so that the sounds seem to occur 'inside' ones head between the ears and not 'at' either ear. Switching the connections to one earpiece will correct phasing. Some listeners can hear a definite difference in intelligibility when the headphone connections to the transformer device are switched around (which reverses 'absolute phase'), the clearer sound has correct 'absolute phase' and is of course preferable. It is generally a one-time adjustment, but not always for every station, program, ect . This can change if the station or studio is careless about engineering practices and allows reversed absolute-phase signals to occur. If you cannot hear a difference when

SELECTIVITY ENHANCEMENT CIRCUITS

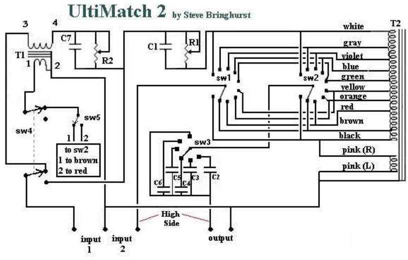
http://makearadio.com/misc-stuff/dxnotes.php
Dave Schmarder’s Hints and tips…

I would like to talk about selectivity enhancement circuits (SEC). Some refer to these as the "Hobbydyne". Jim Frederick in Florida came up with the Hobbydyne circuit. The earliest publication of a SEC I have seen was in Australia in the early thirties. Jim Frederick's Site Here is the Australian page. So you see that what appears to be new, sometimes isn't. But Jim's Hobbydyne was new. Also his first (to my knowledge) recent use of the SEC is credited to Jim.

The SEC and Hobbydyne do the same thing. They allow unloading of the tank circuit, thus increasing the loaded Q, which means better selectivity. It also provides a better match between the tank and diode (and audio circuits further down the line). This is better than the old fashioned way of matching and unloading - tapping the coil. The basic SEC consists of a small value variable capacitor (usually around 20-30 pf), and a small RF choke. I found that a 27 millihenry value is good. Some have used a reverse biased diode in place of the choke. The choke or diode is to complete a DC path so the detector can work properly.

Jim discovered this feature while experimenting with his crystal sets in 2003. He sent me an ie-mail and invited me to test this circuit. I tested it on my, at that time current dx receiver, my #35 radio. It didn't take me very long to see the value in this discovery. I knew that this was going to be a regular part of my dx crystal radio designs, so I looked around for some inexpensive chokes. I found some 27 mh chokes and found they worked great. The next development from Jim was his Hobbydyne circuit. Using the SEC described above had the issue of the resonant frequency shifting when the selectivity was changed. It is easy to understand as the capacitance was being changed and this affected the tuning. Jim's solution was to add a differential capacitor. A differential capacitor is a variable capacitor with one rotor and two stators. As the capacitance on one side increases, the other side decreases. This part was used mostly in the high end variable oscillators for better stability.

Jim later made an enhancement to his basic hobbydyne by adding a small trimmer on the ground leg of the differential capacitor. This allowed for better tracking across the differential capacitor range. I found there are two Hobbydyne hookups. One is what Jim came up with and the other is what I came up with. I don't claim any discovery here, it was most likely a wiring error. But, isn't that how some everyday items were discovered? Below are some circuits showing various SEC configurations. Figure (a. is a directly connected diode to the top of the tank. This is the worst possible way to directly connect a diode for most builders. Only if a high impedance load is used at the output, will this method work well. Otherwise, you can tap the coil and connect the diode to that tap. That way you won't end up with a bad mismatch and severe tank loading. This causes loss of sensitivity and selectivity. Figure (b. is a basic SEC. Just a small trimmer capacitor and a dc path rf choke. This is a good place to start, especially if you don't have a differential capacitor. The rest of the figures show various SEC and the Hobbydyne connections. It is kind of a take-your-pick situation. Figure (e. has the



Directions for use of Ulti Match 2

Input 1
General directions for using the UltiMatch with crystal detector receivers; Crystal detector input is made at input 1 with the diode to SW4 & the detector return to the other terminal. 1st position of SW-4 is for higher impedance detectors and the 2nd position is for lower impedance detector ckts & mineral detectors. SW5 selects an over-all ratio shift to better match some low impedance headsets at pos#2, pos#1 is 'normal'. SW5 doesn't function with SW4 in 'low'. R1 is used to adjust for lowest strong-signal distortion with lower impedance detectors, R2 is adjusted for lowest strong-signal distortion with very high impedance detectors like Schottky barrier diodes, otherwise, it's 'normal' setting is 'minimum' with the adjustments for 'low' SW4 setting and germanium and similar detectors on SW4 'high' being made with R1. SW2 allows selection of the best match, by ear, of the input device

UltiMatch and UltiMatch 2(new)
by Steve Bringhurst

This is a "All in one box" unit
This incorporates the Select to Match ("S-T-M") and the Universal Match-Box ("Uni-Match")
all in one unit. Get the most out of your components!!

Original UltiMatchCircuit
Original circuit has been left here so those who have already built the circuit can see easily the differences in the two circuits.
This will help if you would like to "convert" to the new circuit.

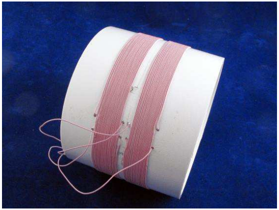
CONTRA WOUND COILS

http://makearadio.com/misc-stuff/dxnotes.php
Dave Schmarder’s Hints and tips…

Hi Friends. Welcome to my contra coil page. The coils that I am showing on this page are used as the main tank coils for crystal radios (and tube radios too). I believe that this improved type of tank coil will be one that you will want to incorporate in your next crystal set. I owe the ideas on this page to Ben Tongue. A while ago he published this very interesting article on his web site. The article describes a radio he built that has a constant receiving bandwidth across the MW broadcast band. Reading this article is very worthwhile.

My goal isn't to have constant bandwidth, but improved performance where it is really needed, at the top end of the band. There are several difficulties in tuning the high end of the band and I believe the contra coil will improve your dx reception.

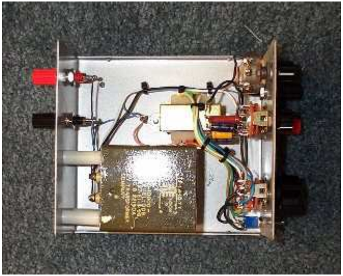


The contra coil in its simplest form is two equal coils wound on the same coil form, but in opposite directions. The coils are connected in series to tune the low end of the band and in parallel for the high end. How the coil is wound and connected is where the secret lies. With the windings wound as they are, the losses are low and the Q is high. The variable capacitor also operates in the sweet spot, further cutting losses. On the high end of the band, the litz strands are doubled with the parallel connection. That's got to be good!

Ben's coils have extra taps for the diode connection. The tap used is dependant on the part of the band that is tuned, along with connecting the coils in series or parallel. He splits the band into 4 segments. For now, I'm leaving off the taps and going with a hobbydyne type circuit that will allow for variable tank loading and matching.

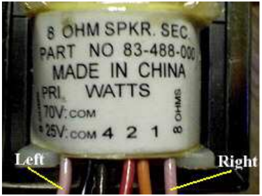
The first coil shown is my test prototype cylinder coil. I felt I should build one cylinder type to get the feel of how this coil will operate. The coil form is a styrene sewer pipe coupler. I bought it at Home Depot. The outside diameter is 4-1/2 inches (11,5 cm). There are 22 turns of 165/46 litz wire on each winding. Each coil calculates out to 27 feet (8,25 m), including 6 inch (15 cm) wire leads. The start (**s**) windings are in the center, and the finish (**f**) windings are towards the form edges. When winding the coil, start at the center. Wind the first coil. Then when winding the second coil, beginning again at the center. The two start windings will wind in the same direction around the form. That makes the coil wound reverse, or contra wound around the form.

To connect the coils in series connect the start of one coil to the finish of the other coil. The other leads are connected to the



put in for 10k Hi "Z" headphones (Radio Shack)

Notes:
1) The range of C1 can be from .05uf to .22uf. It is not that critical.
2) Only ten of the twelve positions are used on SW1
4) #1 lead on T1 goes to SW3. It is split and one lead goes to brown on SW1 and the
other goes to red on SW1. This allows you to shifts the ratio range a full
step for better use of the Stromberg Carlson elements.
5) Experimentation is the key to getting the right values on this unit.
What is right for you and your set up is what counts.
6) See photo below for proper phase ID of the two "pink" wires on the Bogen 725
transformer.



My version of Steve's S-T-M Stanley/Bogen

rest of the circuit. For parallel operation, the two start wires are connected together as the two finish wire are connected together. The connections to the rest of the radio are from these points.

When the coils are in series, the inductances add (plus the mutual coupling). This is because the coils are in phase. It is just that the wiring connections jump to different positions on the forms. When the coils are in parallel, they are also still in phase, but at 1/4 the original inductance value.

The inductance is approximately 240 µh in series and 60 µh in parallel.

It is likely that you will want to use some kind of switch to go from series to parallel. Try to find a low loss switch, such as a ceramic rotary switch, or use thumb nuts, and brass links mounted on low loss materials. The circuit is shown below. It is important that the coil and switch be wired exactly as shown. If your radio doesn't work, check the wiring first. I included the physical wiring pictoral below. This is from my #64 contra radio. The picture of the switch is the top view, while the pictoral is how it is wired from the bottom.

Design Your Own Contra Coil

Now how do you design your own contra coil? Here is the place to start. You may want to skip this part for now and look below at the pre-designed coils. If your tuning capacitor matches one of the situations below, you don't need this section.

You will need a few things before you start. First, bookmark this page on crystalradio.net. This link sends you to Dan Petersen's *Professor Coyle* calculator. This takes nearly all the math out of designing your own coil. You want to select the cylinder coil calculator as this one has the resonance calculator.

If you build a coil, you should have an L/C meter. I use the one produced by AADE. It is important to be able to balance the inductances of the two coils. If you don't have one, you can just shoot for the best by using the designs that I have made.

If you want to test the actual tuning ranges, you will need an accurate signal generator, a capacitance meter and a scope or other rf level indicator. If you are building one coil, you can just put it in your crystal set and check out the tuning range by listening for the stations.

It is best now to go over some of the basic design criteria, map out what we have and discover a few truths and speculate on some assumptions. So here we go:

The contra coil has a 4:1 inductance ratio between series and parallel. 240:60 µh for example.

My version of Steve's S-T-M Calrad/Bogen

The S-T-M is excellent for comparison of headphones. It works very well for one or two sets of phones as well. It will run a range of headphones, from magnetic to sound powered.

The low end of the tuning range should be 530 khz. Better to design to 520 khz. The larger the value of your variable capacitor, the lower this is likely to be.

The high end of the series coil connection should reach above 1000 khz. This may not be possible. Just so the next condition is met, all is ok.

The low end of the parallel tuning should overlap the series high end by 30-50 khz.

The tuning ranges should span the dial over a total of 240-300 degrees.

A variable capacitor as low as 15-280 pF can be used but a higher value is recommended.

The variable capacitor shouldn't be over 500 pF.

Figure on about 25 pF capacitance added by the radio detector circuit and coil distributed capacitance.

An air trimmer capacitor of 75 pF is recommended. This helps with dial spread.

If you build the coil too large, you will lose dial spread but you will tune the whole band.

If you make the coil too small, you may not be able to get that 30-50 khz mid band overlap. (This assumes that you would have to increase the trimmer a lot more.)

The higher that the total maximum to the total minimum capacitance ratio is, the wider the tuning range will be. This means that the dial spread would decrease. Look at the pictures below in the *Other Adjustments* section

Being that the main tuning capacitor range and the fixed added values (diode circuit and coil distributed capacitance) is pre-determined, it comes down to juggling the coil value and the trimmer capacitor value to get the best spread with full tuning range.

R1 250k ohm variable resistor
SW1 12 position single pole rotary switch (Radio Shack)
C1 .1 uf capacitor
C2 Value of C2 depends on the set up of the headsets.
(all non polar)
  1) one 600 ohm impedance element = 1 uf
  2) two 600 ohm impedance. elements wired in parallel = 2.2uf
  3) two 600 ohm impedance elements wired in series = .5 uf
  4) 10k Hi "Z" headphones = .068uf to .05uf
  5) two low "Z" elements in series like Stromberg Carlsons can be run on 2.2 uf, but 4.7uf might be a better match up.

Notes:

1) 1 uF is a good fixed compromise value for C2 if several different impedance headsets will be frequently used.
2) The range of C1 can be from .05uf to .22uf. It is not that critical.
3) Only ten of the twelve positions are used on SW1
4) White lead on T1 goes to the rotary switch SW1 with yellow
5) Experimentation is the key to getting the right values on this unit. What is right for you and your set up is what counts.
6) See photo below for proper phase ID of the two "pink" wires on the Bogen 725 transformer.

S-T-M
"Select to Match"
by Steve Bringhurst

The "Select to Match" was designed to allow a person to experiment with different headphones on the same crystal radio.
If you are using only one set of headphones only, you might want to build the
dedicated circuit below which will save you space, time and money.
STM introduction

L= Coil Under Design - Series & Parallel
C= Main Tuning Capacitor Min & Max Value
Ct= Trimmer Capacitor 75 pf max
Cr= Radio Capacitances, 25 pf fixed

Crystal Radio Contra Coil Design

Here is an example: To start, you have to measure and add the capacitances for when the tuning cap is at minimum and maximum. Add 25 pF for the extra radio capacitances. Also include a starting value of 10 pF for the trimmer setting. The values are reached by rocking the values back and forth until a suitable value for the coil is found.

Let us assume a 15-350 variable capacitor plus 35 pF for the extra capacitances described above. You can see them in the schematic shown above too. This means that the circuit capacitance ranges from 50 to 385 pF. These are starting values, and the minimum and maximum values are likely to be more like 80 to 415 pF as the trials go on. The starting value for the inductor is 240 and 60µh.

Starting with the low end, plug in a value of 240 µH and 385 pF into Professor Coyle. That is a pretty close 524 khz. Lucky, hµH? Ok, now use the 240µh coil and plug in the minimum total capacitance. That comes to 1453 khz. That is too wide of a frequency spread. Instead of going further, we will change the maximum and minimum capacitor value and start over.

Now plug in a higher value of maximum capacitance and adjust the coil value to a 520-530 khz range. Let's try 415 pF. That drops it down to 504 khz with a 240µh coil. Let's reduce the value of the coil. 225µh brings the frequency in at 521 khz. Now let's try the minimum value of 80 pF with a 225µh coil. That sets it at 1186 khz.

Ok, it is time to try the high range. Since the low range is 225µh, the high coil will be about 56 µH. The low end with 415 pF now tunes 1044 khz. We have more than enough overlap, but the parallel coil low end tuning range is a tad high.

So let's go back and turn up the trimmer 20 more pF. This will give us a capacitance range of 100 pF to 435 pF. 225µh with that capacitance tunes 1061 to 509 khz. The 56µh coil and 435 pF tunes to 1020 khz. That is a 41 khz overlap. This looks like a good value to go, but let's make one more tweak.

How about raising the inductance to 232µh. The tuning range is pretty good but the low to high band split is a little higher than I like. The capacitance at 100 to 435 pF is good. Remember that the trimmer will take care of the inaccuracies.

So 230 µH and 435 pF tune to 501 khz and at 100 pF tunes to 1045 khz. The parallel coil is now 58µh. That tunes down to

STANLEY TRANSFORMER COMPANY

Stanley Match built by Mike Tuggle

The StanleyMatch is nothing radically different from other phone matching units, just a way to get more flexibility from the Stanley/UTC TF-1A-10-YY input transformers still available at a bargain from Fair Radio. By some nifty switching, one can combine two single 100 k-to-100 ohm units to get five different input-output impedance pairs. The key component is the 4-pole, 5-position switch. These come in the form of 4-deck rotary switches, as 2-deck switches with two independent 5-position sections on each deck, as shown here (actually, the sections are 6-position with one position blocked out) -- or possibly as single deck switches with two independent sections on each side! On a 4-deck switch several positions will likely need to be blocked out. That's what those tabs at the collar are for.

The 2 x 3 x 5 in. mini-box is about as small as I would suggest going -- unless you are a micro-circuitry freak and/or don't mind the smell of insulation burning on your soldering iron. Even so, I had to pre-wire several of the components before installing them in the box. Details like exact pot and capacitor value and connector types are user's choice. I just happened to have 'standardized' on 1/4-in. phone plugs and 1/8-in. miniature output jack on my sets.

The low impedance (50 - 200 ohms) outputs make this unit especially suitable for low impedance sound powered phones. I suppose you could Bogenize the low impedance end to match higher impedance magnetic phones. I've been quite happy with SP's and haven't seriously tried other types. The test points (TP) mounted on the rear apron are for audio voltage output measurements if so desired.

1002 khz. That is a 43 khz overlap. The trimmer will let you adjust to 1041 to 998 or 5 channel overlap.

Now a couple of things: First, you won't get the coil that close, but if it is plus or minus 5µh, that is fine. The trimmer will iron out the glitches.

Notice that we didn't talk about the high end of the band in the parallel coil configuration. This isn't important as it will always fall above 1700 khz.

You will have good dial spread with these values. The actual dial spread will depend on the shape of the capacitor plates (straight line capacitance, or straight line frequency). You will have better dial spread than with regular wound coil.

If you are unsure, wind the coil on the large side. It can be taken apart and adjusted if you are real far off. It is better to have less dial spread than not being able to tune the band.

This works with a cylinder wound coil or spider coil.

So to recap, we found a **232/58µh coil** would be good with a **15-350 pF capacitor** with a **60 pF trimmer** (with the fixed 25 pF for the radio and coil capacitance).

Recently Jeff Welty whipped up this page for calculating spider contra coil. It is very complete, from entering the data to printing a coil form template.

So here is the calculator. I'm sure this will take the misery and doubt out of your coil building.

I wish you the best success with your coil. (and luck too) :)

Dial Spread

There is a special feature that comes with the contra coils. That is, the tuning range on each band is somewhat wide. This means that a capacitor with a big capacitance ratio isn't really needed. But what happens is that the dial spread is not as good as it could be. Take a look at the two pictures. They are the same radio, kind of a before and after shot.

The top picture shows the tuning covers a much narrower part of the dial scale as the bottom picture. You have to look close at the numbers as the ranges are a little different. The left side is the low band (530 - 1000) and the right side is the high band (900 - 1700).

The difference is that I placed a small trimmer capacitor (about 75 pF maximum) across the main variable capacitor. Now the capacitance ratio of my variable is about 6:1 (90-550pF). Before the ratio was about 23:1 on this capacitor (20-475pF).

The StanleyMatch combines two of the bargain Fair Radio transformers with a 4-pole, 5-position switch to provide several high-to-low impedance matches especially suitable for low impedance sound powered phones.

StanleyMatch by Mike Tuggle

Strombergs are lower AC Impedance than most other sound powered headsets and can
benefit greatly with this circuit. This will help them perform closer to the other "Big Can" decktalkers.
Also works great if using the "mic" elements out of decktalkers.
"Mic" elements are also lower impedance.

I did try a more aggressive type of band spreading using both a trimmer capacitor along with a padder type. But since I am stuck with a fixed 4:1 coil ratio, I had some trouble getting the dial spread to work correctly on both ranges. However with the way I did the dial spread, I get about a total of 2 turns of the knob in each range. A regular coil set, such as my #63 is just under 3 turns of the knob to cover the entire band. Another contravantage.

Your actual situation will be different, depending on the actual components you use. But after you build your set with a contra coil, investigate using a trimmer to widen your dial spread.

BASKET / SPIDERWEB COIL DESIGN

PA2MRX

http://www.pa2mrx.nl/UK/coil%20homebrewing_uk.htm

The tuning circuits of my xtal sets are made out of old fashioned type of coils as seen in old magazines and photo`s, these can be Honeycomb, Basket weave, Spiderweb and other forms of coils. In German these are: Honigwaben, Korbspule, Spinnwebenspule. Basket weave coils are also mentioned in books as "Lorenz" coils, and can be made in different shapes and sizes, as the Honeycomb and Spiderweb coils.
These coils were made because of their low own capacitance, this gives your coil a higher Q because the windings are further apart from eachother, there is more air between the layers.

You can make your coils using enameled copper wire, or silk or cotton insulated wire. Better if you make coils for the middlewave band using Litze wire, this wire is made out of many insulated smaller wires, from 3 up to 1500 or more small wires. But the more wires, the more expensive the wire.

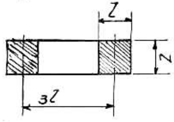

Fig. 19

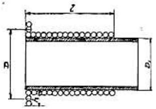

Fig. 20

A honeycomb coil is not more then a one layer cilinder coil. Many variations are made of this type of coil. After many tests and research they came to the conclusion that the selfinduction is going through a maximum when the cross section has a rectangular form (Thickness is same as width) like in fig.19 is the same, and when the average diameter is the same is 3x the thicknes of the winding

Calculation of Spiderweb/basketweave/cilinder coils can be done with the "prof. coyle" programme, but I didn`t find a formule to calculate honeycomb coils, these calculations were so complex they only published the data to create these honeycomb coils. I have the data below as found in old books:

Used capacitor in table 1 is 1000cm (+/-1100pF) wire size 0,5mm. The coil form has a diameter of 5cm, thickness is 4cm.

# Windings	Wire Length	Wavelength
25	4m	180 - 430 meter
35	6m	200 - 550 meter
50	9m	250 - 700 meter
75	14m	400 - 1000 meter
100	20m	500 - 1300 meter
150	30m	700 - 2000 meter
200	42m	1000 - 2700 meter
250	50m	1300 - 3600 meter
300	63m	1600 - 4200 meter

Source : Bastelbuch fur radioamateure, 1925

Coilform in table 2 is 5cm in diameter and a width of 2,5cm. Own wavelength is the wavelength of the coil with its own capacitance.

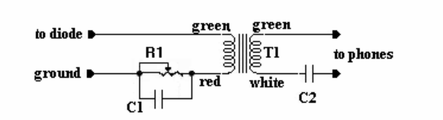
Winding #	I mH	Self WL m	Wire mm	WL m	Range with C 50-1000pF m
25	0,05	50	0,56	4 meter	90 - 400

DEDICATED IMPEDENCE MATCHING CIRCUITS

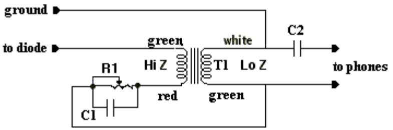
Darryl Boyd

http://www.crystalradio.net/soundpowered/matching/index.shtml#Dedicated

This "fixed" setup is designed for standard 600 ohm impedance elements wired in series.
It is a standard matching transformer circuit.



The following is another dedicated circuit for two 600 ohm series wired elements.
The transformer is set up more as a autoformer.
I think it performs a little better than the above circuit.



Try both circuits. They use the same parts!

T1	Calrad 45-700 audio transformer (Ocean Electronic)
R1	250k ohm pot (a mini pot would work great!)
C1	.1uf capacitor

35	0,09	90	0,56	6 meter	120 - 550
50	0,16	110	0,56	9 meter	175 - 750
75	0,3	150	0,56	14 meter	250 - 1000
100	0,6	200	0,56	20 meter	300 - 1500

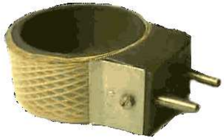
Source: Der radioempfangsapparat, 1924

Coils as in the upper tables are made on a coilform as seen on description and photo`s below, but you can alter these by varying number of pegs used.



The Honeycomb coil

Coil form with its measurements are in the following drawings. You can use your own measurements and the number of pegs. But the above values are for these coils here.

You can make your form out of wood, but I made it out of alluminium on a lathe, the pegs are made out of knitting pins, bought these at the weekly market here, if you buy these with 2 pointed sides you can make two pegs of `m, so you need to buy half of the knitting pins you need for the coil form.

Figure 55—Layouts of a heart-shaped cam.

I also made a aircoil out of 6mm copper brake piping, 11cm in diameter, 8 windings, space between winding is 6mm.

These type of coils were used very often in old radio equipment.

Self resonance at 17.690Mhz, -3db point at 17.980 and 17.350, makes a bandwidth of 630Khz.

Q of this coil at 17.690Mhz is 17.690/0.63=28

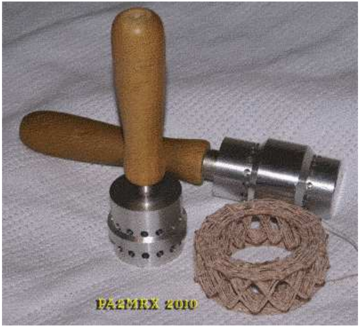
How do I get I veeery high Q at shortwave,..I think never, even a aircoil I made with a diameter of 25cm had a low Q.

21-7-2008

I also made myself a coil winder according to the Gingery Coil Winder manual. With this type of winder you can make yourself some nice small radio coils for your project.

The coil winder in the above links are in principle the same as the Gingery winder, only the cam has been changed into a heart shaped one. This type of cam has the advantage that the wire does go around the circumference of the coilform in a triangle shaped fashion, instead of a sinus with the round excentric cam. The heart shaped cam gives the coil a much higher stability when winding the coil. Below a scan from WM. Querfurth`s book of the heart shaped cam with the round excentric cam in red to compare the two cams.

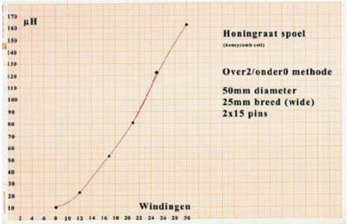
If you use only one side of the coil form, you can wind your spiderweb coil on this coilform, but you have to fix it with glue, the needlework will not work here.



November 2010
On a lathe I made two new coilforms to wind coils. Both have two rows of 15 holes in it to put in some knitting pins to wind the wire around.

The sizes are as mentioned in old books for the coils mentioned above, one 4.5cm thick and one 2.5cm thick with a inner diam of 5cm.

Winding method: Over two, directly to other side and again over two at the other side. (over 2/under 0)



I wound the smallest coil mentioned above (2.5cm wide). Precisely according the description in the books with 25 windings. The value should be 50µH, but after I measured it with my AADE meter and another LCR bridge the value was around 122µH. Same for wire length, I took 4 meters and wound the coil till I got no wire left,..8 windings with a value of 12µH. So just wind your coil, measure and put some more wire on it or take some windings off till you get what you want.

For the above honeycomb coil I made a table for future use when I need to make some coils. I made 3 and put the value and windings on mm-paper, I connected the points to get a rough guess of inbetween points.
Then I made the coils I needed and measured them and also put them inside the table. It only goes to 162µH because I didn`t wind a bigger one.

Table is for honeycomb coils using the "Over2/Under0" method, wound onto a 5cm in diameter form, 2.5cm wide with 2x15 pins.

was resonant at 11.110Mhz. -3dB point was at 11.220 and 10.930, this makes a bandwidth of 290khz.

.

So this is the frequency where the coil is resonant with it`s own capacitance. The Q of this coil is 11.110mhz/0.29mhz=38
Not really a good choise to use for a chort wave crystal receiver.

Its own capacitance is approx. 13pF.
If I use this coil on shortwave, the selectivity would go any better then this 290khz. Q is only getting better at a lower frequency.

I also measured the self resonance of my 440x46 spiderweb coil of my 2006 BTTF receiver.

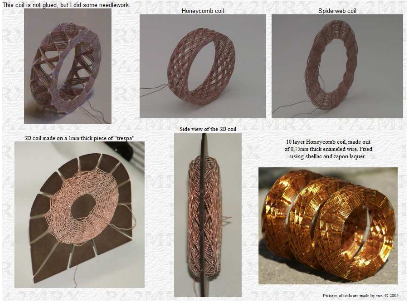
Resonant at 2.523Mhz, -3dB point at 2.539 and 2.505Mhz, this makes a bandwidth of 34Khz.

The Q of the coil at this frequency is 2.523/0.034=74.

Here I see that the Q is much better at lower frequency as i measured in another chapter on my site.

Self capacitance is around 16pF

If I wanted to make myself a 10-15Mhz shortwave crystal receiver with a bandwidth of around 9Khz, then I
would have to use a coil with a Q of around 1300, this means a self resonance point that is at a much higher level, and
a even lower capacity,..even lower as 5pF,..I still want to seperate the station,..won`t I.



This coil is not glued, but I did some needlework.
Honeycomb coil
Spiderweb coil
Side view of the 3D coil
3D coil made on a 1mm thick piece of "trespa"
10 layer Honeycomb coil, made out of 0,75mm thick enameled wire. Fixed using shellac and zapon laquer.
Pictures of coils are made by me. © 2005
PA2MRX

Pictures of coils are made by me. © 2005

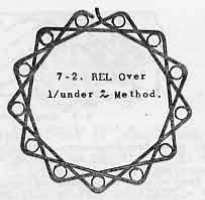
Fixation of the coils so they do not fall apart can be done using some needlework, another used methode from the beginning of the 20th century is to fix the coil using "zapon-laquer". This a laquer on a nitrocellulose basis. Long time ago you could make this yourself by dissolving celluloid film negatives into ethanol. Beware: film negatives these days are not made out of celluloid. Now you submurge the coil into the solution you get and after that you get it out of the solution and let it dry. You also can use "shellac" to fixate the coils, this is available plentyfull on Ebay,..a kilo for 8 Euro`s or so.

Self resonance of coils

I made a cilinder aircoil with a value of 15µH. Without a capacitor connected I measured the resonance of this coil. It

The basket weave coil. (lorenz coil)

You can create your basket weave coils using a piece of wood or something. I used a piece of plexiglass with a thickness of around 1cm and drilled holes in it, I used steel nails to put in the holes. The nails are placed in a cicle of around 12cm. I wound the wire around the nails using the over1/under2 methode. But this can be re-arranged by you using anothe method,..over1/under1, over1/under3,..you name it.



7-2. REL Over
1/under 2 Method.

over2/onder methode

Another type of coil is the basket weave coil made using two rings of nails to wind your wire through. At the right you see 2x11 steel nails. The methode of winding here is over2/under2, but you also can use over1/under2 or something else.

Note: Of you follow the wire in the over2/under2 methode, you get to the starting point after 3 circulations of the wire. Now you layed down just one layer. This also includes the coils mentioned above.

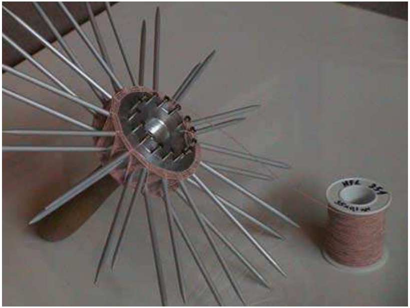
This is what they mean by the windings do not see eachother, there is lots of air between every layer, this gives you a coil with a better Q.

This way I made several basket weave coils and some of these had one layer after 8 windings.

In table 1 they used 25 windings and 4meters of wire on a coilform of 5cm in diameter. These 25 windings are the windings,..not the layers. You have to watch out not lay down 25 layers.

A basket weave coil stays the same diameter while the width is getting more.

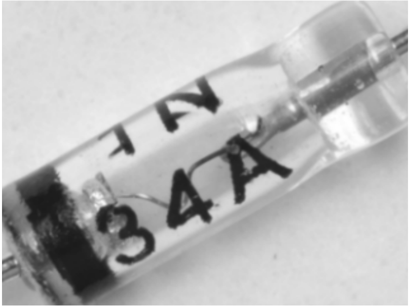
Below some pictures of coils I made and on their form. (this is my first and old coilform)



Coil being made using the form with knitting pins

KEVIN'S WEBSURFER HANDBOOK III
FOR CRYSTAL RADIO

DIODES:
SOLID-STATE & VACUUM



Kevin Smith
2011

Printing / Binding Instructions

KJ Smith

NOTES:

INTRODUCTION

The contents of this second handbook concern themselves primarily with diodes, diode theory, and aspects of older vacuum diodes. The rectifier diode forms an essential part of the crystal radio circuit, it has a fascinating history, and few parts of the set deliver as much confusion (to me at least) and speculation, comment and even controversy. This document results from my web explorations of diode theory in general and diodes as crystal radio rectifiers in particular. Additionally, I have held a certain fascination with the vacuum diode ever since when reading on the history of radio, I found that this rectifier was actually discovered and patented prior to the lowly galena crystal from which the sets take their name.

In this booklet I have taken the sections and pages that I spend much/most time studying and have arranged them into sequence from basic theory and design considerations to more advanced material and finally on specifically vacuum diodes in particular. Some vacuum tube chapters were especially painful to include as they required pasting in each page of a scanned document. Still, I felt, and feel that this document is especially worthy and useful as a source of vacuum diode theory. Each section is useful and understandable to the hobbyist with moderate to good experience. The handbook will help the beginner to quickly get up to speed and allow the experienced builder to find endless new ideas. This is not a book of Hookups or circuit designs, that is covered in my Catalog of Crystal Hookups, nor is it a tutorial on Crystal Radio, that can be found in my Handbook Volume 1.

Much of the material in this handbook is copyright for which I have not sought permission. Therefore this is not presented for publication or copy, and certainly not for profit. It is only my personal resource. I encourage anyone finding this copy to pursue ON THE WEB the web pages identified within. I include the name of the author and web address of each section. I wish to sincerely thank every author presented for their excellent pages and ask forgiveness for my editing into this handbook.

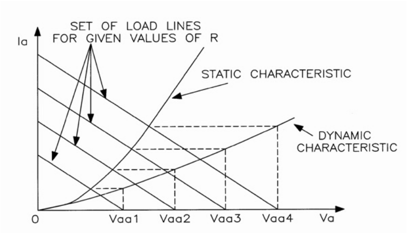
and assuming a constant value for the load Rl then, by drawing a separate load line for each value of supply voltage, the dynamic characteristic can be obtained, as shown below.

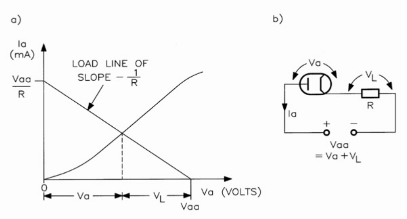


SET OF LOAD LINES
FOR GIVEN VALUES OF R
Ia
STATIC CHARACTERISTIC
DYNAMIC
CHARACTERISTIC
0
Vaa1
Vaa2
Vaa3
Vaa4
Va

Obtaining the dynamic characteristic for a diode valve and its load.

The points on the dynamic characteristic are obtained by projecting, horizontally, the intersection of a load line and the static characteristic until it in turn intersects a vertical line drawn from a supply voltage value. Since the dynamic characteristic is drawn for a range of values of the supply voltage, this implies that the latter is varying, in other words it is an alternating supply rather than DC, as is the case in rectification.

current in the circuit will vary by using a graphical construction.



(a) The load line for a diode valve. (b) the diode in series with a linear resistive load.

The second image shows the diode in series with its load and defines the voltages and currents in question. A 'load line' of slope -l/R is drawn between the two points: Ia = Vaa/R Va = 0 and Ia = 0, Va = Vaa. As in solid state practice, the end points of a load line define zero conduction and maximum conduction, the latter being dependent upon the values of supply voltage and load resistance. Any other points on the load line imply intermediate levels of conduction. By dropping a construction line from the intersection of the load line and the static characteristic, we can see how the total supply voltage Vaa is divided into the two separate voltages Va (the voltage across the diode) and Vl (the voltage across the load).

The Dynamic Characteristic

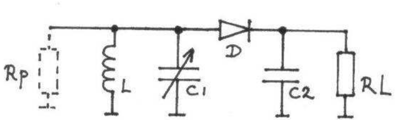
By taking a number of different values of supply voltage Vaa (as would happen if the supply was alternating, for example)

How to build a sensitive crystal receiver

Dick Kleijer crystal-radio.eu
http://www.crystal-radio.eu/engev.htm

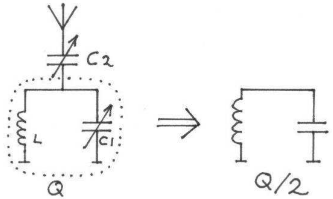
[Calculator included at the bottom of the web page to calculate the components of your receiver for maximum sensitivity at weak signals].

In this article some information about the design of a crystal receiver with maximum sensitivity.



Circuit diagram 1
Circuit diagram of the crystal receiver, which we are going to design for maximum sensitivity at weak signals.
This can be a detector circuit of a 2 circuit receiver.
But also a receiver with loop antenna.

RP represents the losses in coil L and tuner capacitor C1



Circuit diagram 2
If an antenna is connected via a matching network (in this case C2) to the LC circuit, this will reduce the circuit Q.
When optimal matched to the antenna, the Q will be halve the value of the unloaded Q (of L,C1).
For a calculation of the values of C1 and C2, click here.

For the calculation of maximum sensitivity: replace the LC circuit + antenna by a LC circuit with an unloaded Q equal to halve the original value.
Coil value L stays the same.

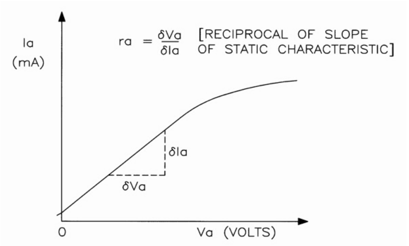
You get maximum sensitivity if there is maximum power transfer from LC detector circuit to load (loudspeaker).
The LC circuit has a certain parallel resistance RP, this is not a real resistor, but a virtual resistor caused by the losses in coil and tuner capacitor.

If we know the Q-factor of the detector circuit, and the induction of the detection coil, we can calculate the value of RP as follows:

RP = 2.pi.f.L.Q (Ohm)

The Anode Slope Resistance ra

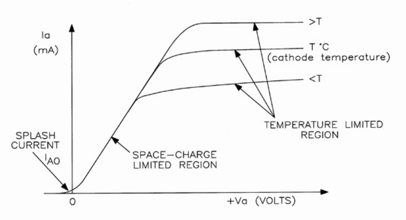
It is worth introducing this parameter at this time since it is one that we shall make use of later in discussing the performance of more complex valves. It is defined as shown below,
Defining anode slope resistance for a diode valve.



and is the value of resistance obtained by dividing a small change in anode voltage by the corresponding change in anode current. It is therefore the reciprocal of the slope of the static characteristic, and varies with the operating point, although fairly constant over much of the space charge limited region. This is a real value of resistance, since it represents the opposition of the valve to alternating quantities.

Series Circuit Operation

It is usual to operate a diode valve, which is clearly a non-linear device, in series with a resistive load, the latter being a linear device. It is possible to predict how the voltages and



The static characteristic of a diode valve.

Above three curves have been drawn for different values of cathode temperature, although in practice, as explained earlier, the cathode is held at a constant temperature.

It is interesting to note that:

A) The current is not exactly zero when the anode voltage is zero, but has a value (Iao) of a few micro-amperes. This is known as the 'splash current' and is the result of a few high energy electrons that manage to cross the inter-electrode gap even without an attracting potential.
B) In the space-charge limited region, the characteristic is nearly linear (actually following the 'three-halves' power law: Ia is proportional to Va-3/2).
C) In the temperature limited region there is little change in la even though there are large changes in Va. This is because the anode is collecting electrons at the same rate as they are being emitted by the cathode.
D) No significant current flows when the anode is negative with respect to the cathode.

pi = 3.14
f = the frequency (Hertz).
L = induction of detector coil (Henry = H).
Q = the quality factor of the unloaded LC circuit.

The value of RP is depending on the frequency, use for instance the value of RP in the middle of the frequency range. For medium wave for instance, we can use the value of RP at 1 MHz.

Maximum power transfer from LC circuit to load.
If the load resistor RL was directly connected across the LC circuit, it would be simple:
maximum power transfer would occur if RL=RP.
The loaded Q of the LC circuit is then halve the value of the unloaded Q.

But of course we also need a diode between LC circuit and load RL, to demodulate the RF signal.
In the rest of this article we assume the RF signal on the LC circuit is not modulated, so the output of de diode is a DC voltage.

Maximum sensitivity at strong signals.
With a very strong signal across the LC circuit, the diode shall work in the linear detection region.
If the input voltage is high enough, the diode will give only very few power losses, compared to the rectified power.
In the calculation (with strong signals) I assume the diode has no losses at all.
This can in practice not be reached, but it rather simplifies the calculations.

If the diode has no losses, the DC voltage across the load resistor will be equal to the peak voltage of the RF signal.
This peak voltage is 1.41 times the RMS value of the input signal.

In this situation, maximum power transfer to the load RL will occur if:
RL = 2 x RP
The loaded Q of the LC circuit is then halve the value of the unloaded Q.

However with strong signals, maximum sensitivity is not a very important subject, output power is already high enough to be heard.
We can better design the receiver for maximum sensitivity at weak signals.

Maximum sensitivity at weak signals.
When receiving (very) weak signals, the diode shall work in the square law detection region.

Diode Static Characteristics

We now start getting into the ways in which specifications for thermionic devices are presented. For the diode, these illustrate clearly the dependence of anode current upon anode voltage.

passed forward into semiconductor phraseology - cathode, anode, emitter, collector!).

Since electrons are negative charged particles, they will only be attracted to the anode if this is given a positive potential with respect to the cathode. This explains why the valve only conducts in one direction, from cathode to anode, and not vice versa. It also explains the choice of the word 'valve' to describe the device, since a valve is, by definition, a one-way device. The Americans, however, never cottoned on to this terminology and always refer to them as 'vacuum tubes'.

The magnitude of the current flowing in a diode depends upon the number of electrons emitted and the magnitude of the voltage applied to the anode (known as the anode voltage Va). The amount of electron emission depends upon the temperature of the cathode, which is fixed by the voltage supply to the heater, this being a constant value. The only true variable is, therefore, the anode voltage. The action of the latter in controlling the anode current can be explained as follows.

As we now know from the foregoing, the cathode is normally surrounded by a cloud of electrons known as the space charge. With zero anode voltage there is no current flow, and there is a state of equilibrium between the electrons being emitted and those falling back onto the cathode's surface, The application of a small positive voltage to the anode causes some of the space charge electrons to be attracted to the anode, resulting in a small anode current flow. The gaps created by these electrons leaving the space charge are filled by further emission from the cathode. Electrons arriving at the anode flow to the positive supply terminal, while at the same time an equal number of electrons leave the negative supply terminal for the cathode. This gives rise to a continuous current flow around the circuit,

The input of the diode behaves like a resistor with value RD parallel to the LC circuit.
The diode output is like a DC voltage source in series with a resistor RD.
Maximum power transfer from DC voltage source to load RL occurs when: RL = RD.

In the square law detection region, the detected DC voltage is proportional to square of the RF input voltage.
The power in the load resistor is proportional to the square of the detected DC voltage.
In other words, the power in load RL is proportional to the 4th power of the voltage across the LC circuit.
So it is important to make the voltage across the LC circuit as high as possible, this is done by making the impedance of the loaded LC circuit as high as possible.

If we make all impedances equal, so RL = RD = RP the loaded Q of the LC circuit would be equal to 0.5 times the unloaded Q.
The voltage across the LC circuit is then also 0.5 times the unloaded voltage.
The output voltage is then proportional to: 0.5^4 = 0.0625
If we however make RD and RL 3 times as high, so RL = RD = 3xRP the loaded Q of the LC circuit will be 0.75 times the unloaded Q.
The voltage across the LC circuit is then also 0.75 times the unloaded voltage.
The output power is then proportional to (0.75^4)/3 = 0.3164/3 = 0.1055.
We divide by 3 because the load resistor is now 3 times higher.
So we now have 0.1055 / 0.0625 = 1.6875 times more output power (compared to the situation: RL = RD = RP).
And also, the loaded Q is now 1.5 times higher, so a better selectivity for the receiver.

In the next Excel file: diode.xls the relative output power is calculated for many values of RD and RL, where RD=RL=3xRP is the most sensitive combination.

Conclusion: At weak signals there is maximum power transfer from LC circuit to load, so maximum sensitivity for the receiver if:
RL=RD=3xRP The loaded Q is then 0.75 times the unloaded Q.

Increasing the circuit Q

Increasing the unloaded Q of the LC circuit, will make the impedance of the LC circuit higher.
Because of this the voltage across the LC circuit will increase, the diode then will work more efficient, and output power increases.
More information about increasing the Q, you can find here.
Very good crystal receivers make use of LC circuits with an unloaded Q above 1000.
A high Q also gives a selective receiver.

Increasing coil induction

The impedance of the LC circuit can also be increased by increasing the coil induction (μH value).
However making the induction higher, can also result in a lower circuit Q, compensating a part of the impedance increase.
And a lower Q of course gives worse selectivity.
Practical values for induction of medium wave receivers are 200-300 μH.

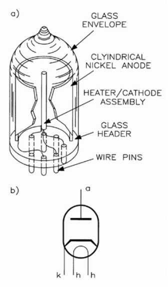
Valve Technology - A Practical Guide
A series of articles from 1993 by Graham Dixey C.Eng., MIEE republished by kind permission of Maplin Magazine.

The Diode Valve

The diode valve is so called because it has just two electrodes – the cathode and the anode.



(a) Construction of a modern diode valve (indirectly heated type), (b) circuit symbol for a diode valve.

These correspond to the two electrodes of the original diode valve mentioned above, the cathode being the electrode that is heated and emits electrons, and the anode being the electrode that collects the electrons (notice also that these terms have

Choice of the diode

If we know the diode resistance RD, we can calculate the diode "saturation current" (Is value) with the formula:

Is = 0.000086171 x n x TK / RD

Is = saturation current of the diode in A
n = ideality factor of the diode, if you don't know the value, then take n=1.08
TK = temperature in Kelvin (= temperature in ºC + 273)
RD = diode resistance in Ω

Now search for a diode which has a Is value close to the calculated Is value.
Or connect several diodes with a low Is parallel, to reach together the desired value.
More information about diodes you can find here.

Diode connected to a tap on the coil.

The best sensitivity is always reached if the diode is connected to top of the LC circuit, and RL=RD= 3xRP.
But not always it will be possible to make the load resistance RL high enough.
If we don't have a load (audio transformer) with a high enough impedance, the LC circuit will be loaded to heavy, and the Q will reduce.
A method to prevent this, is to connect the diode on a tap somewhere on the coil, instead of the top of the coil.
The Q of the loaded circuit then will increase.
With the calculator at the bottom of this page (click here) the effect on output power can be calculated when using a tap on the coil.

Audio transformer.

When making a receiver with a high Q factor, the load resistance will have to be very high, for instance some Mega-Ohms.

In that case we need a transformer which transforms this high impedance down to the impedance of the used loudspeaker.

Transformers with such a high input impedance are hardly to find.

They can however be self made, look for instance at my transformer unit 2

At high input impedances, in practice both efficiency and bandwidth of a transformer will reduce.

Loudspeaker

Of course we use a loudspeaker with a sensitivity as high as possible.

More information about this, you can find here.

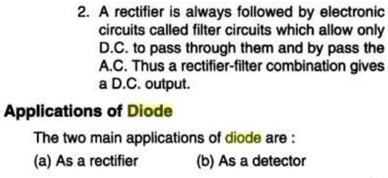
Calculate optimal components for detector circuit

With calculator 1, diode and load resistor are calculated for which the sensitivity of the detector circuit at weak signals is maximum.

Fill in the yellow coloured fields, and click on "calculate calculator 1".

These values can then be taken over in calculator 2.

Then you can self change in calculator 2 all parameters of the detector circuit (all yellow fields), and calculate the effect of this on sensitivity and loaded Q.

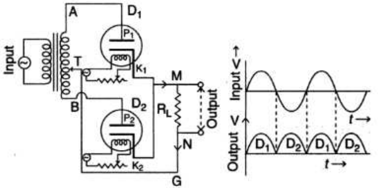


2. A rectifier is always followed by electronic circuits called filter circuits which allow only D.C. to pass through them and by pass the A.C. Thus a rectifier-filter combination gives a D.C. output.

Applications of Diode

The two main applications of diode are :

(a) As a rectifier (b) As a detector



(i) Circuit (ii) Input-Output waveforms

positive. Therefore, the second diode conducts but the first remains passive. Thus, the two diodes conduct alternately. But in both half cycles of A.C., the current in load resistance R_L flows in the same direction. So, we get continuous D.C. at output. For full-wave rectifier,

Note :

$$I_{D.C.} = \frac{2I_0}{\pi}$$

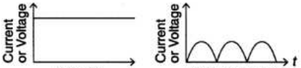
$$I_{rms} = \frac{I_0}{\sqrt{2}}$$

$$\eta_{max} = 81.2\%$$

Ripple factor, $r = 0.48$

The output of rectifier is fluctuating or pulsating. To make it smooth, filters are used.

Notes : 1. The output obtained from a half wave or full wave rectifier is not a pure D.C. but it is a pulsating D.C. (mixture of A.C. and D.C.)



(i) (D.C.) (ii) Pulsating D.C.

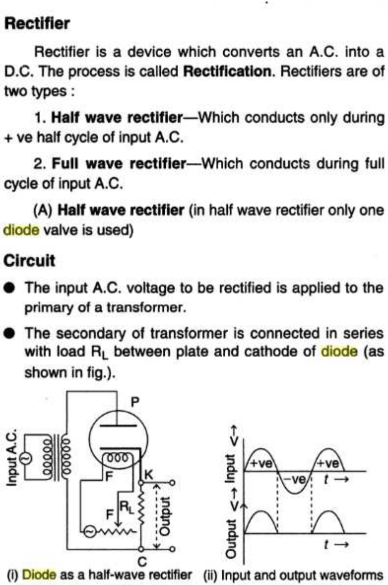
Operation

- A.C. input is applied the plate 'P' becomes positive and negative alternately.
- For the positive half cycle of input, the plate is positive with respect of cathode. So that diode conducts and plate current flows through the tube load R_L and secondary. So output occurs across load. R_L as shown in fig. (ii).

Important Points

- During – ve half cycle of A.C. input, →Plate is negative with respect to cathode. So the diode does not conduct, and no voltage appears across output.
- For half wave rectifier; (I_0 is peak value of current)
  - → Average value of current $I_{D.C.} = I_0/\pi$
  - → Root mean square value of current $I_{rms} = I_0/2$
  - → Maximum efficiency $\eta_{max} = 40{\cdot}6\%$
  - → Ripple factor $r = 1{\cdot}21$

(B) **Full wave rectifier**—It converts full A.C. into D.C. In this rectifier two diodes are used which conduct alternately. The output is obtained across the load resistance R_L. Here in first half cycle of A.C., plate of first diode remains positive and plate of second diode remains negative. Hence, the first diode conducts and the second does not. In second half cycle of A.C., plate of the first diode becomes negative and that of second diode becomes



Rectifier

Rectifier is a device which converts an A.C. into a D.C. The process is called **Rectification**. Rectifiers are of two types :

1. **Half wave rectifier**—Which conducts only during + ve half cycle of input A.C.

2. **Full wave rectifier**—Which conducts during full cycle of input A.C.

(A) **Half wave rectifier** (in half wave rectifier only one diode valve is used)

Circuit

- The input A.C. voltage to be rectified is applied to the primary of a transformer.
- The secondary of transformer is connected in series with load R_L between plate and cathode of diode (as shown in fig.).

(i) Diode as a half-wave rectifier (ii) Input and output waveforms

Diode "saturation current" Is = nA at ºC
Diode resistance RD = kΩ at ºC
Output power at weak signal = dB with regard to calculator 1
Output power at strong signal = dB with regard to calculator 1
Loaded Q at weak signal = X with regard to calculator 1
Loaded Q at strong signal = X with regard to calculator 1

Example 1.
We have a LC circuit with a 200 µH coil, the unloaded Q is 1000 and the frequency is 1000 kHz.
As load we use a 100 kΩ audio transformer, because this is the only one we have.
What is the output power at weak signals compared to the optimal load resistor.

Fill in the following values, in calculator 1:
f = 1000 kHz
L = 200 µH
Q = 1000
Click on "calculate calculator 1" (The optimal load resistor and diode are now calculated).
Click on "take over values from calculator 1"

Change load resistor RL in calculator 2 in 100 kΩ.
Click on "calculate calculator 2"
We now see the sensitivity at weak signals is 9.97 dB lower compared to the optimal load.
It's also interesting to see, the Q at strong signals is only 38

Example 2.

We have 2 receivers, both with a 200 µH coil.

One receiver has an unloaded Q of 100, the other receiver has an unloaded Q of 1000, at 1000 kHz.

Both receivers have optimal diode and load resistor.

What is the difference in output power between the 2 receivers?

Fill in the following values, in calculator 1:

f = 1000 kHz

L = 200 µH

Q = 1000

Click on "calculate calculator 1" (The optimal load resistor and diode are now calculated).

Click on "take over values from calculator 1"

Reduce the Q in calculator 1 to: 100.

Click on "calculate calculator 1" (The optimal load resistor and diode are now calculated).

Click on "calculate calculator 2".

The result is, the high Q receiver gives 1000 times more output power (+30 dB) at weak signals.

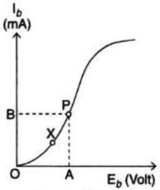
At strong signals, the difference in output power is 10 times (+10 dB).

Example 3.

We have a simple crystal receiver, with a 200 µH coil, and an unloaded Q of 200.

As diode we use a germanium diode with Is = 400 nA (at 25 ºC).

The load resistor is 47 kΩ.

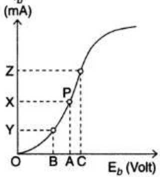


as D.C. plate resistance. The D.C. plate resistance R_p is given by

$$R_p = \frac{OA}{OB}$$

Note : Since plate characteristic curve is not a straight line—Therefore, D.C. plate resistance is variable. Hence, D.C. plate resistance may be calculated at the actual operating point.

(ii) **A. C. plate resistance**—The ratio of a small change in plate voltage across a diode to the resulting change in plate current is known as A.C. plate resistance.



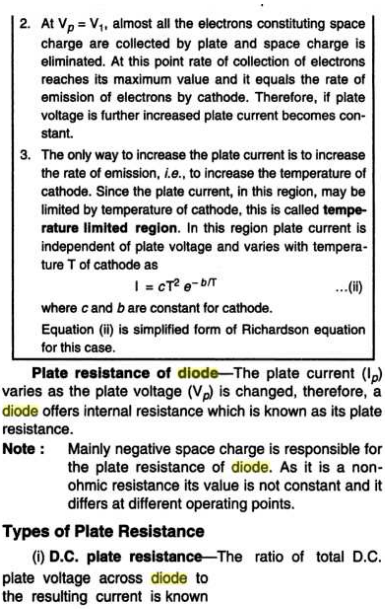
$$r_p = \frac{\Delta V}{\Delta I}$$

Note : The A.C. plate resistance at operating point P can be found by considering small equal changes of plate voltage on either side of the operating point (*i.e.*, AB = A.C.)

Change in plate voltage = BC

Change in plate current = YZ

$$\therefore \text{ A.C. plate resistance at } p,\ r_p = \frac{BC}{YZ}$$



2. At $V_p = V_1$, almost all the electrons constituting space charge are collected by plate and space charge is eliminated. At this point rate of collection of electrons reaches its maximum value and it equals the rate of emission of electrons by cathode. Therefore, if plate voltage is further increased plate current becomes constant.
3. The only way to increase the plate current is to increase the rate of emission, *i.e.*, to increase the temperature of cathode. Since the plate current, in this region, may be limited by temperature of cathode, this is called **temperature limited region**. In this region plate current is independent of plate voltage and varies with temperature T of cathode as

$$I = cT^2 e^{-b/T} \qquad \ldots\text{(ii)}$$

where *c* and *b* are constant for cathode.

Equation (ii) is simplified form of Richardson equation for this case.

Plate resistance of diode—The plate current (I_p) varies as the plate voltage (V_p) is changed, therefore, a diode offers internal resistance which is known as its plate resistance.

Note : Mainly negative space charge is responsible for the plate resistance of diode. As it is a non-ohmic resistance its value is not constant and it differs at different operating points.

Types of Plate Resistance

(i) **D.C. plate resistance**—The ratio of total D.C. plate voltage across diode to the resulting current is known

We are going to compare the sensitivity at 1000 kHz, with a high quality receiver, with L = 200 μH and unloaded Q = 1000.
This receiver has optimal matched diode and load resistor.

The values of the simple receiver can directly be entered in calculator 2.
We don't have to calculate first the optimal load and diode, because this receiver isn't using optimal load and diode.
So, in calculator 2 we fill in:
f = 1000 kHz
L = 200 μH
Q = 200
Is = 400 nA (at 25 ºC).
RL = 47 kΩ.

Fill in the values of the other receiver, in calculator 1:
f = 1000 kHz
L = 200 μH
Q = 1000
Click on "calculate calculator 1" (The optimal load resistor and diode are now calculated).
Click on "calculate calculator 2" the differences between both receiver are calculated.

Result: the simple receiver has 29 dB less output power at weak signals.
The simple receiver has a loaded Q of only 60 (at weak signals).

At strong signals, the loaded Q even reduces to 17, but with such a low sensitivity it's unlikely to get a strong signal across the LC circuit.

We note from fig. (i) that curves coincide at low voltage (in space charge limited region) but saturation current increases as shown by portion CD of characteristics.

(2) **Low voltage characteristics**—The plate current is practically zero at zero plate voltage (however, plate current is not exactly zero). If we measure plate current using a micro-ampere plate current of the order of few micro-ampere occurs. This is due to "the fact that even at zero plate voltage a few electrons may have sufficient K.E. to reach the plate and constitute a plate current of few micro-ampere." From the fig. (ii) the plate current becomes exactly zero at a particular negative value V_C of plate voltage, called **cut-off voltage.** The max. kinetic energy of emitted electron is related to V_C as :

$$K_{max} = e V_C$$

Important Points

1. If we increase plate voltage from zero volt to a value V_1 in steps, more and more electrons are attracted from space charge to plate (though at the same time same no. of electrons are emitted from cathode so that space charge is maintained) so plate current increases. As the plate current is limited by space charge, this region of curve is called **space charge limited region**. In this region, plate current is related to plate voltage by equation.

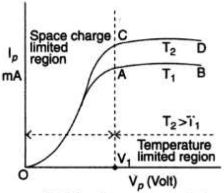
$$I_p = K . V_p^{3/2} \qquad ...(i)$$

where K is a constant.

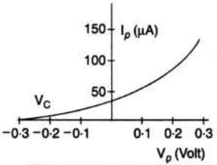
Equation (i) is known as **Child-Langmuir's law.**

V-I characteristics of Diode

(1) **High voltage characteristics**—Fig. (i) shows high voltage plate characteristics when plate current is measured in (mA). Keeping temperature of cathode constant, say (T_1) (*i.e.* filament current constant) when plate voltage increased from zero volt in steps and corresponding value of plate current i_p measured in m.A. the variation occurs as shown in curve OAB. If the cathode temperature is increased from T_1 to T_2.



(i) High voltage characteristics



(ii) Low voltage characteristics

Crystal Set Analysis

by Berthold Bosch, DK6YY

http://www.oldradioworld.de/gollum/analysis.htm

(First published in German in 1993/94; see references at end. Updated 12/03/2002)

(See some of Berthold Bosch´s realized xtal sets here)

Contents: 1.Voltages and Powers in Set, 2. Antenna/Earth as Signal Source, 3. Set with Parallel- Tuned Circuit, 4. Diode Properties, 5. RF Matching, 6. AF Matching, 7. Computer Simu- lations, 8. Series-Tuned Circuits .

Since my schoolboy days I have been fascinated by crystal radio reception: radio in its most basic form. However, in many cases I was not really satisfied with what I read on the subject in the literature. In the treatises I came across, the descriptions often remained rather vague, presenting little convincing foundations. Partly they were rather speculative and even presented contradicting conclusions. For this reason I found it advisable to carry out my own investigations. My intention was to obtain more quantitative results, for example as regards the best diode and the understanding of the obvious interdependence between the radio-frequency (RF), audio-frequency (AF), and DC subcircuits, what it meant for an optimum design. In the following I present results obtained over the years. Only medium-wave reception is considered.

1.Typical Values of Voltages and Powers in Set

Let us first see of what order of magnitude the RF and AF voltages and powers are which we have to deal with.

According to amplitude-modulation theory, the AF power contained in the total AM signal of power PRF is given by m2

PRF / (2+m2) where m is the modulation factor. If we assume m=0.5 we thus have 11 percent of AF power in the AM signal. Sometimes broadcasting stations use modulation factors of up to m=1 (100 percent) which then causes a correspondingly higher AF power component. At my urban location, in the West of Germany (Ruhr District), the strongest station (15 km away) produces an electric field strength of 0.18 V/m and, with my antenna and earth arrangement, an RF power of about 3 mW is available in the crystal set. Hence 330 µW of AF are contained in the RF if we assume m=0.5. A practical (linear) diode detector coupled to a tuned circuit delivers 70 to 80 percent of this to the AF load. This means that ideally I can expect about 240 µW of AF being available from my local station, sufficient for moderate operation of a loudspeaker.

In the crystal set that I am going to investigate (Fig. 2 below) I measured the following RF voltages across the tuned circuit when RF and AF matching existed (Secs. 2, 5 & 6):
a) Tuned to the local station (WDR 2, 720 kHz, 200 kW, 15 km away):8.9 V

b) From of my "district station" (DLF, 549 kHz, 100 kW, 35 km, field strength 40 mV/m, 0.2 mW of RF power):2.3 V.

c) At night - with a wave trap for the local station - more than a dozen stations appear from all over Europe with 1 to 5 mV/m, producing 130 mV across the circuit as a mean value (0.5 µW of RF). Such low voltages will move the working point over only a rather limited part of the diode characteristic where the relative curvature is low. Consequently, the detector efficiency now drops to below one percent.

d) Good headphones produce an audible signal down to 10 pW of applied AF power.

plate current. These electrons flow through the external circuit and finally return to the cathode, thus making up the supply of electrons lost by emission. On increasing plate potential more electron will gain sufficient kinetic energy so as to reach anode, hence the plate current increases.

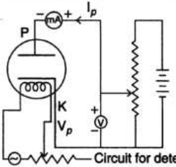
Important Points to Note

- The current flows in the diode only when plate is made positive relative to cathode.
- No current can flow when plate is negative relative to cathode.
- Within a diode electrons can flow only from cathode to plate.
- Due to unidirectional conduction property the diode acts like a valve.
- The diode automatically starts conduction when the plate is positive or stops conduction when the plate is negative (due this property) the diode may act as a rectifier, converting A.C. into D.C.)

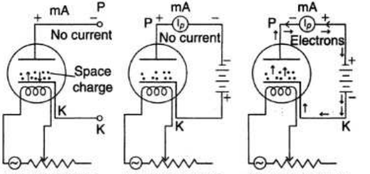
Characteristics of Diode

Characteristics of vacuum diode can be best studied by finding the relation between plate voltage and plate current for a given cathode temperature.

The circuit for determining the plate characteristic of an indirectly heated vacuum diode is shown in fig.



Circuit for determining plate characteristics of diode



(i) Plate is open (ii) Plate is given –ve potential (iii) Plate is given +ve potential

(1) **Anode (plate) at zero potential relative to cathode**—This situation is shown in fig. (i)—The emitted electrons do not have sufficient kinetic energy so as to reach the anode. However, a few electrons may reach the anode on account of their kinetic energy, constituting negligible current. The emitted electrons accumulate near the cathode and form a cloud of electrons. This is known as space charge. At a certain stage the number of electrons forming the space charge becomes constant for a given operating temperature. This space charge becomes a source of electrons that can be attracted to the plate, if it is at a positive potential.

(2) **Anode (plate) at negative potential relative to cathode**—This situation is shown in fig. (ii). The emitted electrons are repelled back due to retarding potential of anode. For a particular negative potential of anode plate current may be zero.

(3) **Anode (plate) at positive potential relative to cathode**—This situation is shown in fig. (iii). The electrons constituting the space charge are attracted to the plate. This flow of electrons from cathode to plate is known as

Employing a signal generator and using a sensitive diode (see below) I found that an RF power of about 10 nW is required to generate this 10 pW of lower-limit AF. The detector efficiency has at this very low RF level thus fallen to a mere one per mille. Obtaining an RF power of 10 nW in my set requires a field strength of about 0.3 mV/m. According to estimates based on groundwave propagation theory, a 1000 kW transmitter operating near 1500 kHz should generated 0.3 mV/m at a distance of 190 to 200 km; the electric field strength is roughly proportional to Radicle (PTX)/(f2d2), where PTX = transmitter power, f = frequency, and d = distance. The particular example is chosen because at 1440 kHz I can during the day just hear the signal of RTL Luxembourg, being 195 km away and reported to radiate 1200 kW. The voltage measured across the tuned circuit was 40 mV in this case. To be able to receive RTL I carefully have to suppress the local as well as the district station.

e) When I connect an AF amplifier to the crystal set, a number of stations located about 150 to 250 km away can additionally be heard via groundwave propagation in the daytime. The diode thus provides (some) detector action at RF levels even lower than 10 nW. But the AF power generated is then too small to produce an audible signal in the phones directly.

The above numbers show the considerable variations in the RF voltage generated across the tuned circuit. Hence it is not surprising that a crystal diode found to be best suited for DX reception is not necessarily the optimum choice for achieving best loudspeaker operation from the local station. But before I present results on diode behaviour I am going to describe the circuit I employed. Let us start with antenna and earth as an integral part of the total circuit.

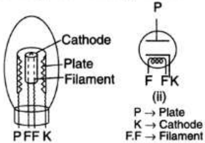
Vacuum Diode or Diode Valve

A vacuum diode consists of two electrodes : a cathode; and an anode enclosed in an evacuated glass tube. Its operation is based upon thermionic emission, it is also called thermionic diode.

Anode (or plate)—The anode is a hollow cylinder made of Ni or molybdenum and surrounds the cathode.

Cathode—A cathode may be directly heated or indirectly heated type. Usually an indirectly heated cathode is provided (except in high power application).

As shown in fig. (i) an indirectly heated cathode is in the form of nickel cylinder coated with oxides of barium or strontium. Inside the cathode, a heater filament of tungsten is inserted.



(i) (i) Construction of diode
(ii) Symbol of diode

Fig. (ii) shows it symbol :

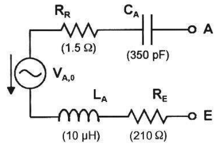
Operation of diode—When electric current is passed through the diode it emits a large number of electrons. These emitted electrons may be accelerated or retarded by applying positive or negative potential to anode relative to cathode.

when the tube is in operation. It can just be seen glowing orange in the diode portion of the tube. On one side is the diode with the triode on top; on the other is the pentode, all of which are clearly displayed. The tube cost $3.10, an excellent price considering all the experiments that can be done with it.

The center tap of the input transformer is not used in this circuit. The triode has grid leak bias. It is not possible to measure this bias with a DMM because of the large grid resistor, but the plate current is only about 280 µA. The diode and triode are referred to the negative end of the filament, but cathode bias is provided for the power pentode. The bias in operation is about -9.3 V, giving a plate current of about 5 mA and a screen current of about 1 mA. The output transformer can be any transformer on hand. I used the P-T31 that has been used in other places, which matches 8Ω to 5 kΩ. The load resistance should preferably be about 12 kΩ. However, it drove a good speaker at considerable volume with a rather small input. A three-tube battery radio could be made with this tube, an IF amplifier stage, and a pentagrid converter, a tube type which will be treated next.

---

2. Antenna and Earth as Signal Source



(Fig. 1: Equivalent circuit of antenna/earth combination.)

I use an inverted L-type antenna of 43 m length, about 10 m above ground. The earth connection is provided by three metal rods of 2 m length each, driven into marly, i.e. a not particularly well conducting, soil. The antenna/earth combination can be represented by the equivalent circuit shown in Fig. 1, giving measured values for the various elements. The antenna capacitance is denoted by CA, the inductance by LA, RE is the earth loss resistance, RR the radiation resistance, and VA,O the antenna source voltage. The two last elements increase in value with the antenna's height and length. For the source voltage I measured a value of 1.6 V, using a selective RF voltmeter. The knowledge of this quantity, which is produced by the strong local station, permits to easily determine the earth resistance. For it 210 ohms were obtained, a relatively high value. Reducing it by installing a better ground system would pay high dividend. Note added in 2002: Meanwhile I installed an extensive counterpoise net in the garden as earth terminal. This reduced the earth resistance to about 25 ohms, with an associated marked increase in available RF power.

Maximum power is transferred to the load, i.e. from the antenna to the crystal set connected to A-E, when we arrange for impedance matching and for resonance in the resultant antenna/earth series circuit. The set will presents, in general, an inductance which is too small for achieving resonance in the antenna circuit. Therefore, an additional coil must be inserted (Fig. 2). The resistance of about 400 ohms in the series-tuned circuit (200 ohms source resistance plus 200 ohms resistance of set when matched) yields a Q-factor of only 4. But this is still helpful regarding sensitivity, but also selectivity (sharpness of tuning), since the delivered current (voltage) is increased by this factor of 4, meaning 16 times in power.

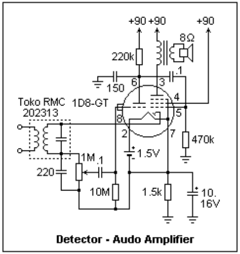
3. Crystal Set with Parallel-Tuned Circuit

As a sort of "standard set" I used and investigated the popular arrangement shown in Fig. 2 which employs two tuned circuits. The inductance LC couples the antenna to the coil of the tuned circuit, the degree of the variable coupling chosen so that matching is achieved. The fixed L1 has a somewhat larger value than required for tuning the antenna/earth circuit of Fig. 1. The variable capacitor C1 is then used for tuning to resonance. The numbers for L1 and C1 apply to my particular case. C3 serves as AF storage capacitor for obtaining a maximum of AF amplitude at the phones, and it additionally provides a short for the RF. In practice, however, it often can be omitted without audible drop in AF. - To be able to properly match the diode detector to the parallel-tuned circuit, the detector branch is hooked up either to the top of coil L2 (wound with Litz wire onto a suitable ferrite rod) or to one of 11 taps provided on it. In this way the diode can be connected, via a switch, to 12 resistance values along the tuned circuit. Such a fine adjustment was required for the investigations reported in Sec. 5. The unloaded tuned circuit has a resonance resistance of 105 k ohms (at 1000 kHz), which drops to 52 k ohms when matched to the antenna/earth. (These are not particularly high resistance values because of the many leads from the taps to the switch.) According to the switch position chosen the diode can so be connected to 12 resistance values that vary between 52 k ohms and 100 ohms. When the diode is set to the tap that provides matching the total resonance

---

circuit at the left. AVC is essential when diode bias is used, to keep the bias voltage in the proper range. The audio signal, of course, rides on the bias connection. Diode bias is not suitable for high-mu triodes such as the 6AV6 or 6AT6, since they are very sensitive to the bias level. The 6R7 is a medium-mu triode ($\mu = 16$). The 6SR7 is a single-ended equivalent, and will also work in this circuit. The signal generator should be adjusted to peak the output, at 455 kHz. I obtained an audio output of 13 V peak-to-peak with a 30% modulated AM signal of 0.2 V peak-to-peak, for a gain of about 289. The tuned circuit provides a large part of this gain.

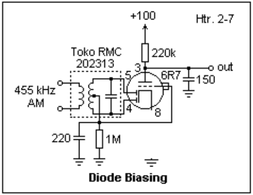
The 6AQ6, 6AT6 and 6BF6 are all miniature dual-diode triodes with the same basing as the 6AV6, the 6BF6 being medium-mu and more appropriate for diode bias and transformer coupling. The 6SQ7, 6SR7 and 6ST7 are similar octal tubes, again all with the same basing. This was a very popular and useful tube type, with many options available.



Detector - Audo Amplifier

The 1D8-GT diode-triode-pentode was designed to provide a complete audio system for a battery-powered radio. The circuit is shown at the right. The filament takes 0.1 A at 1.4 V, easily supplied by a D cell. The B+ supply is 90 V, for which batteries were available, consisting of 60 small cells. This circuit has a drain of less than 7 mA, which is quite acceptable, and hardly more than a transistor radio with the same audio output. The filament is hard to see the plate of the 6AT6. The RF ripple was negligible, but there was some 60Hz pickup, not surprising with a high-gain breadboarded circuit out in the open. It was interesting to show the AM signal and the audio output simultaneously on the oscilloscope.

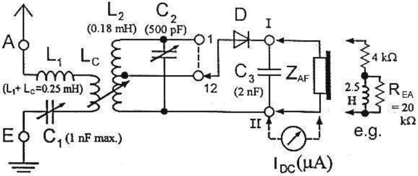
The circuit will function without the tuned circuit, as you can easily demonstrate. The signal generator output must then be increased, because the resonance gain is considerable. The circuit will also function with both diode plates connected to one side of the secondary, and the 1M potentiometer and filter capacitor to the other side. In this case, the ripple frequency will be halved, but the output voltage will be doubled. There is not a great advantage in using a full-wave detector. Look at the DC voltage across the potentiometer as the input amplitude is changed. This voltage, negative with respect to ground, can be used for AVC, automatic volume control, as is discussed elsewhere. With the full-wave detector, it varied from -0.5V for 10V p-p audio output to -1.0V for 30V audio output. In practice, the AVC voltage is further filtered to remove the audio.



The rectified signal voltage is of the correct polarity to provide grid bias for the amplifier tube in this circuit. Therefore, the grid of the triode can be connected directly to some point on the diode load resistor that provides the proper bias, in place of the volume control potentiometer and coupling capacitor shown above. This arrangement is called *diode bias*, illustrated by the

---

resistance then drops to 26 k ohms. - On the right in Fig. 2 the equivalent circuit of the headphones is given which we require later on.

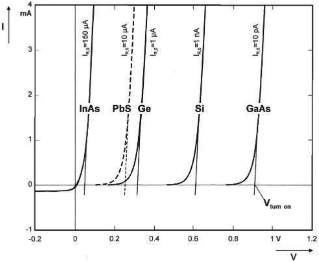


(Fig 2: Wiring diagram of crystal set with parallel-tuned circuit and tuned antenna/earth.)

We have now the task to match (1) on the RF side the diode branch, via the tuned circuit and the antenna coupling, to the antenna source, and (2), regarding the AF, the phones or the loudspeaker to the diode. Both procedures are strongly interrelated. But first we must find out more about the diode and its dynamic resistance.

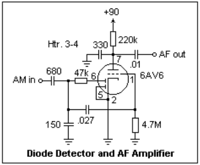
4. Crystal-Diode Properties

All semiconductor diodes principally show a dependence of current I on applied voltage V (static characteristic) like I=IR,0*exp (V/nVT) - IR,0, where IR,O denotes the reverse saturation current at high negative voltages, VT the temperature voltage of 26 mV at room temperature, and n an ideality factor between 1 and 2.



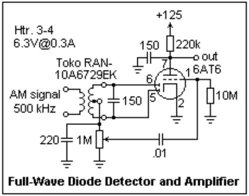
(Fig. 3: Theoretical current-voltage characteristics of various p-n diodes; equal diode areas assumed.)

Reverse breakdown is neglected. The relationship applies to both to p-n diodes and to Schottky diodes. However, the composition and physical meaning of IR,O differs completely for these two diode types (diffusion current resp. field current). Important is the fact that the exponential rise of the diode current occurs the faster, i.e. the turn-on voltage (as a kind of threshold) becomes the lower, the higher the saturation current IR,O is. Calculated characteristics for p-n diodes made from germanium, silicon, two modern compound semiconductors and from galena (PbS) are given in Fig. 3, assuming equal diode areas. The associated reverse currents are stated. The difference in diode behaviour is caused by differing electronic material properties (band gap). Real curves, in particular of the natural crystals, are flatter because of parasitic elements, mainly of diode series resistance. Regarding low turn-on voltage a galena p-n crystal diode is theoretically even slightly better than one made from germanium.



Diode Detector and AF Amplifier

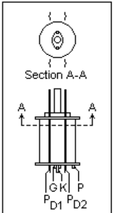
A detector-amplifier circuit is shown at the left. This circuit is fed by a signal generator at AM in, and the audio output is taken from AF out. The amplifier uses grid-leak bias, which effectively clamps the peak of the audio wave at 0 V. The stronger the input signal, the more negative the grid bias, which makes the most of what is there. With an AM input of peak value 0.95 V and modulation amplitude 0.37 V, the peak to peak output was 3 V, for a gain of -8, which is quite good. I used a radio frequency of 2 MHz, and modulation of 1 kHz. At lower radio frequencies, the filtering of the output becomes progressively worse; this could be optimized if desired. This detector gives good fidelity with high sensitivity.



Full-Wave Diode Detector and Amplifier

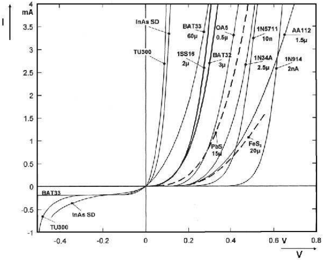
A full-wave diode detector is shown at the right, using transformer input. The 6AT6 is similar to the 6AV6, but its mu is 70 instead of 100. The transformer is a Toko RAN-10A6729EK, available from Digi-Key. It is specified as 0.63 mH, and for 200 kHz. Adjust the signal carrier frequency until the tuned circuit resonates; in my case, this was 500 kHz. For an input signal from the signal generator of 0.18V peak-to-peak (modulation amplitude 0.04V), I got 26V peak-to-peak at

The typical superheterodyne receiver used a diode detector, followed by an audio voltage amplifier. These functions were usually combined in a single envelope, the diodes and the amplifying triode or pentode sharing the same cathode. A very good tube of this type was the 6AV6, whose structure is shown at the right. The diode plates are at the top of the envelope, with the cathode easily seen between them. The IF output was usually from an air-core, slug-tuned transformer, making it easy to use full-wave rectification. Only one of the diodes could be used for half-wave rectification, which was usually quite adequate. The triode is a high-mu triode with a maximum plate voltage of 300 V, and maximum plate dissipation of 0.5 W. The maximum cathode current is not specified, but should not exceed a few milliamperes. The tube has an unusually high plate resistance, and the amplification factor is over 100. It is a good triode for a voltage amplifier. My example gave g_m = 1.3 mS, r_p = 67k, μ = 90 at about 500 μA plate current, and V_g = -1.0 V. The transconductance varies strongly with plate current, reaching 2.2 mS at 1 mA, where μ = 116.



6AV6 Structure

For Schottky diodes principal curves like those in Fig. 3, relating to a particular crystal material, cannot be given. In their case the characteristics strongly depend on the kind of the metal electrode and on the processing parameters. But measured curves for Schottky as well as for p-n diodes are given in Fig. 4, including fairly good examples of galena (PbS) and iron pyrite (FeS) detectors; see also the Table below for identifying the diode types. Again one notices the relatively low turn-on voltage of the two natural crystals which equal or even are below that of the germanium diodes 1N34 and OA5, thus being well suited for low-level detection. (Fig. 4: Measured current-voltage characteristics of various semiconductor diodes (reverse currents indicated))



Very interesting is the performance of modern low-barrier Schottky diodes made from silicon, like the NEC 1SS16 (almost identical: 1SS99, BAT32, BAT63), which show turn-ons at 0.15 to 0.18 V. And, indeed, they show superb performance at low levels. One should expect that the InAs Schottky diode (which was specially made for my experiments) and the TU 300, a backward diode made by

Siemens, would according to the curves shown be even more sensitive detectors. But this is not the case.

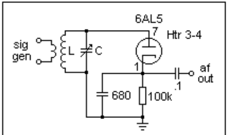
As mentioned, a low turn-on voltage is inevitably associated with a high reverse current. This current reaches values of a few hundred µA for the InAs diode, as also for the TU300 and the Schottky diode BAT33. If the reverse current, i.e. an unwanted back current, reaches such high values we have strong counteracting effects, and ultimately the detector action disappears completely. Anticipating the results of computer simulations described in Sec. 7 one can state that diodes like the 1SS16 show the optimum relation between low turn-on and still acceptable reverse current, thus making them the best choice of presently available diodes as regards detector sensitivity.

To show and compare the capability of various diodes the Table summarizes values of measured AF voltages and of rectified currents, for 1 and 100 µW of available RF power. A power of 1 µW is in my set typical for DX stations at night, and 100 µW for stations 30 to 50 km away. As is seen the 1SS16 leads the field. - For 3 mW of RF (my local station) I obtained with a 1SS16 a DC current of 715 µA, which increased to 1.85 mA in the short-circuit case (AF/DC load = 0), and to 2.95 mA when under these conditions the set was retuned.

---

positive in a resistance-coupled amplifier, disturbing the bias. This is not a maximum in the same sense as the maximum plate dissipation or maximum cathode current are, since damage to the tube is not in question. There is no trouble in the grid leak detector, and values of several megohms are permissible.

There is no analogy to the grid-leak detector with FET's, which otherwise behave pretty much like vacuum tubes, because the leakage current is far too small for the desired behavior. As a gate-bias detector, however, the FET is suitable, and a BJT biased near cutoff makes an excellent detector, as we saw in the page on Amplitude Modulation.



Diode Detector

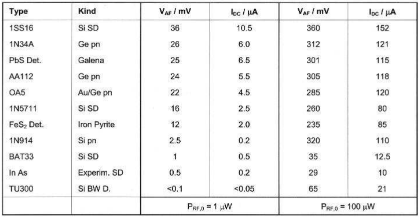
A diode detector, using a standalone diode, is shown at the left. The output is the same amplitude as the modulation on the carrier that is input, very closely, so the detector could not do any better. Often, the diode was included in the first AF amplifier tube, sharing the same cathode, and dual diodes were also available for full-wave detection, which doubles the output. If you have a tuned circuit at this point, it would be easy to test a diode detector, and high voltages are not required, just the heater power. A solid-state diode would work the same way, but the 0.7 V drop would make it less sensitive, and it would not even respond to weaker signals. Using a Ge diode (1N34A) would help, but not eliminate, the problem. The thermionic diode is ideal in this application.

coupled by about 9 turns slipped over the loopstick, providing an AM signal about 30% modulated with 1 kHz, in the broadcast band. The output was roughly constant, no matter what the plate voltage (45 to 105 V), input amplitude, value of grid resistor (from 1M to 3M) or grid capacitor (100 pF to 220 pF). The grid bias with no signal was about -0.5 V with a 1M grid resistor.

The circuit works by using the small grid current when the grid is slightly negative. This grid current increases rapidly and very nonlinearly, so square-law detection is possible. The grid resistor establishes a quiescent point around which the signal oscillates. The rf part is bypassed through the grid capacitor, while the af part remains and causes a voltage drop across the grid resistor, which is then amplified in the usual way. With a 100k plate resistor, the output af voltage could approach 1 V peak-to-peak. Another stage of audio amplification would give a quite satisfactory result, but I was hoping for one tube. (The 12AX7 has two triodes in the same envelope--if such a tube were used, the receiver would be, strictly speaking, single tube.) With most other kinds of detectors, such a hope would be quite vain, it must be admitted.

If the input signal amplitude is increased, the grid bias starts to decrease because the grid becomes positive on the peaks, and the detection becomes a little more linear. If the grid is biased to cutoff with a C supply, then there is clear linear detection, since the signal is effectively rectified. Such a circuit is called a grid-bias detector, and the signal amplitude must be restricted so that the grid does not go positive, when distortion would result.

You may notice in the tube manuals that a "maximum grid resistance" is given for a tube; for the 6J5, it is 1M. The reason for this is positive ion current, which may drive the grid more



Type	Kind	V_{AF} / mV	I_{DC} / µA	V_{AF} / mV	I_{DC} / µA
1SS16	Si SD	36	10.5	360	152

		$P_{RF,0} = 1\ \mu W$		$P_{RF,0} = 100\ \mu W$	

(Table: Measured values of AF voltage (across phones of 4 k at DC) and of rectified DC current for various diodes and two levels of RF power)

Sometimes a DC bias from a battery is applied for shifting the operating point of the diode closer to the turn-on voltage and so improving the detection efficiency. By this method the AF voltage obtained can be increased, for example when using the 1N5711 and the 1N914 at low RF levels. The 1SS16 group of diodes, however, hardly gains from a DC bias. Only at RF powers below about 200 nW I was able to measure a certain rise in AF voltage. At the lowest detectable RF level of 50 nW (Sec. 1), the AF voltage increased by 20 percent (i.e. power by 45 percent) when the optimum bias was applied. But this effect was measurable only, being still too small to be noticed by the ear.

Note added in Jan. 2002: Backward diodes (BWD), like the TU300, are good detectors at extremely low RF signal levels, below about 1 nW with associated voltages of only a few mV. This is due to the relatively sharp bend in the BWD characteristic at zero volts. The generated AF signal is, however, too small for operating phones directly and calls for an AF amplifier. Then stations can be copied which are not heard when in such a set-up with AF amplifier a "normal" sensitive diode, like the 1SS16, is used instead of the BWD.

5. RF Diode Resistances and RF Matching

For achieving best performance it is required to RF match the diode to the tuned circuit. The dynamic resistance of the diode depends on the amplitude of the RF voltage applied to it, and on the kind of AF load impedance.

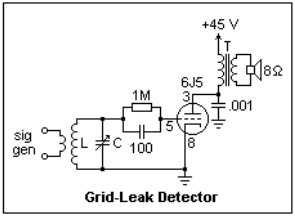
In AM tube radios the detector diode operates at a high level (linear detection) and has a load consisting of a large (ohmic) resistor shunted by a small capacitor. Calculations show that in this case the RF diode resistance, as presented to the tuned circuit, is roughly half of the ohmic load resistance. In a crystal set the calculation is somewhat more complicated since there the RF voltage on the diode is generally lower and the diode load is more complex (see equivalent circuit of phones in Fig. 2). Hence I preferred to measure the RF diode resistance RD. The measurements were carried out under actual working conditions using a signal generator. Figs. 5(a) and (b) show the results obtained for high-impedance phones with 4 k ohms DC resistance and for low-impedance ones with 120 ohms, respectively. The RF frequency used in these measurements was 1000 kHz, the modulation frequency 1 kHz with a modulation factor of 0.4 (given by the signal generator). Figs. 5 give the measured diode resistances, as a function of the RF power applied, for an 1SS16 (also some in parallel), a silicon p-n diode 1N914, and for natural galena as well as carborundum (silicon carbide; SiC) crystals. The diode circuit was in turn connected to the various taps on the coil L2 .When the RF voltage measured across the tuned circuit dropped by a factor of radicle (2)=1.41 compared to its value without diode, matching was achieved. Then the RF diode resistance equalled the RF resistance of the tuned circuit at the tap point. To avoid

---

Unfortunately, I do not have any actual circuits that used a 1V6, but the amplifier shown at the left may be studied. It gave a gain of -14 with a plate current of 357 µA, so the effective transconductance was 298 µS. I substituted a 100k plate resistor, but the gain only increased marginally, to about -17. By experimenting, you may be able to get more gain from the tube. At low plate currents, the amplifier oscillated in an odd manner, and there were other peculiarities seen while fiddling around, but I did not take the time to track them down.

The Grid-Leak and Diode Detectors

Detectors are discussed in Amplitude Modulation, where the two types of square-law and linear are explained, and the grid-leak detector is mentioned. A circuit using a 6J5 triode is shown at the right. The audio output transformer T can be replaced with a 10k or 100k resistor, and the output observed with an oscilloscope. I could find only a 1k to 8Ω transformer, really designed for use with transistors. The circuit works, but I was not impressed by its output. Asking for loudspeaker output from a detector is being very optimistic, but I had some hopes. Perhaps a more suitable transformer would give better results.



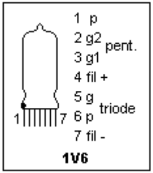
Grid-Leak Detector

The tuned circuit can be one from a crystal set, with a loopstick and variable capacitor. The signal generator is

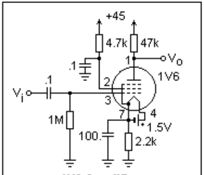
These tubes make vacuum-tube experiments very easy without requiring high-voltage supplies, only what is found in a normal transistor lab.

Sub-Miniature Tubes

The smallest regular electron tubes were the *subminiature* tubes, designed for battery-powered portable apparatus, from hearing aids to radiosonde transmitters. Typically, the lead wires were brought out through the press seal without a base, but there was also a subminiature base used for a few tubes. As an example, you can work with the 1V6, a pentode-triode with a filament taking 40 mA at 1.25V (the filament supply can be a D cell). The tube is 40mm x 10mm x 7mm, approximately. The maximum plate voltage is 45V, and typical plate currents are less than 1 mA.



A sketch of the 1V6 and its connections is shown at the right. On the press seal, there is a red dot that identifies what I have called pin 1. The filament is located at the center of the tube, with the pentode on one side and the triode on the other. The triode shows a μ of about 10, r_p = 18.6 kΩ, and g_m = 440 μS. The pentode has g_m as high as 694 μS above 500 μA plate current, but it drops considerably at lower plate currents. The two devices can be tested as usual, taking care not to exceed 45V or 1 mA. Note that the pentode and the triode share the same filamentary cathode.



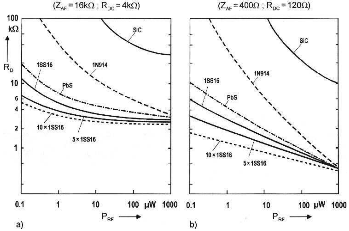
1V6 Amplifier

---

an error one must readjust the coupling to the antenna when the diode is connected to the first found (V/1.4) tap point and then repeat the search for the now somewhat altered (V/1.4) tap. A second iteration further improves the result, but not much.

As in principle to be expected from the characteristics, the diode resistances vary rather widely, from some 100 ohms to some 10 k ohms, with lower values obtained when the DC resistance of the phones is low. The galena detector shows values only moderately higher than those of a single 1SS16. The silicon diode 1N914 presents high values due to its high turn-on, which even more applies to carborundum.

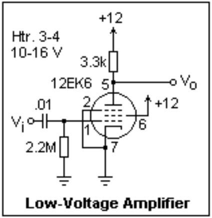
(Fig. 5:Measured RF diode resistances versus available RF power: (a) for high-impedance phones (4 k ohms at DC), (b) for low-impedance phones (120 ohms at DC)



The data obtained then indicate that the optimum tap position on coil L2 (for matching) depends on the diode type, the strength of the received station, and on the DC resistance of the phones. The larger the value of the diode resistance is, the higher must the tap position be up the coil. Sometimes it was suggested in the literature to have a fixed tap at a point of about 1/4 to 1/3 of the windings counting from the earth point. In the present case the tuned circuit has a resistance of approximately 6 k at the 1/3 tap point. As Fig. 5a shows, this indeed is a rather good choice for a galena detector when high-impedance phones are used and weak stations received. Impedance matching requires that the reactances of source and load cancel out. But in our case the resistance of the tuned circuit has no reactive part at resonance, and the reactance of the diode, caused mainly by the diode junction capacitance of at most a few pF, can be neglected.

Connected to a particular tap, the diode resistance is (auto-)transformed up and appears in parallel to the resonance resistance of the tuned circuit. This means that not all of the available RF power reaches the diode since a reasonable fraction of it is dissipated in the resistance of the tuned circuit. In order to really transfer the maximum of power from the antenna to the diode branch, the diode (of generally low resistance compared to that of the tuned circuit) should be connected untapped to the top of the coil L2. This, however, strongly reduces the selectivity of the set and requires a readjustment of the coupling of the tuned circuit to the antenna. With high incident high RF power (and/or low impedance of the phones) the tuned circuit can, under these conditions, become loaded to such an extend that variations of the capacitor C2 have no tuning effect any longer, which means that C2 is obsolete and can be omitted. The diode circuit is then aperiodically coupled to the (tuned) antenna circuit, while the coil L2 merely acts as the secondary winding of the transformer which matches the diode to the antenna.

6. AF Matching



Low-Voltage Amplifier

The 12EK6 (also known as 12DZ6 and 12EA6) is a screen-grid pentode for low-voltage use. A voltage amplifier using this tube is shown at the left. This tube was generally used as an IF or RF amplifier, so the load would have been a resonant circuit, not a resistor, giving much higher gain. However, the resistive load is easy to experiment with. There is no voltage to waste for cathode bias, so grid-leak bias is used. When a signal is applied, the bias will adjust itself so that the top of the input waveform is clamped to 0 V. Vary the input amplitude to verify this. This circuit works with an input of up to about 2 V peak-to-peak, perhaps best for an input of around 1.0 V p-p. The output voltage is then about 5.8 V p-p, the plate potential is 6.0 V, plate current 1.8 mA, and gain about -5.5, corresponding to a transconductance of 1.8 mS, about right from measurements of the characteristics and the position of the operating point in this case. The transfer characteristic is rather curved, leading to considerable distortion for larger amplitudes. Nevertheless, it is remarkable that the circuit works so well at such a low voltage.

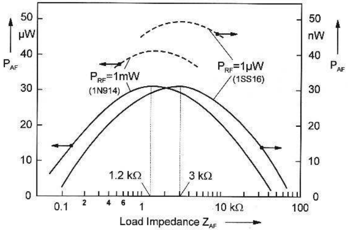
As a triode (plate, suppressor and screen connected together), the 12EK6 has $\mu = 8.5$, $g_m = 6.3$ mS and $r_p = 1.35$ kΩ. The transconductance varies considerably with plate current, which gives rise to distortion for large signal amplitudes.

current, which was stepped up by a transformer and then rectified to DC again (sometimes by contacts on the vibrator) for the B supply. Vibrators were electrically very noisy, and had short lives, but were widely used until solid-state equivalents became available. They came in cylindrical metal cans, and looked like electrolytic capacitors. The 0Z4, mentioned elsewhere, was a rectifer specifically for vibrator supplies. Another possibility was the *dynamotor*, a motor-generator with a single rotating armature and brushes, which could supply more power than a vibrator and was more reliable. However, they were too expensive for general commercial use, though widely used in the military.

When 12 V became the automotive standard, vibrator supplies or their solid-state equivalents, could still be used. Tubes with 12.6 V heaters were already common. Many had the heater center-tapped, so they could be used equally well on 6.3 V. However, 12 V is high enough to be used directly as the plate supply if the tubes are specially designed. A range of tubes was produced that could be used on 12 V only, without any high voltage at all. We have already discussed the 12DL8 and 12K5 space-charge-grid tetrodes, and how the space-charge grid allows larger plate currents for small plate voltages. There were approximately 15 tube types designed for 12V use, of which only three, the 12DL8, 12DS7 and 12K5 are space-charge grid tetrodes, behaving like triodes. The other tubes are of conventional construction, in general having low plate currents, less than 1 mA in many cases. These include twin-diode triodes (12AE6, 12FK6, 12AJ6), sharp cutoff pentodes (12AF6, 12BL6, 12CX6, 12EK6), remote cutoff pentodes (12CN5, 12DZ6), twin-diode remote cutoff pentode (12F8), pentagrid converter (12AD6), pentagrid (variable gain) amplifier 12EG6, and a twin-diode power screen-grid tetrode, 12J8. The last tube can deliver 20 mW output power, half of what the 12DL8 can do.

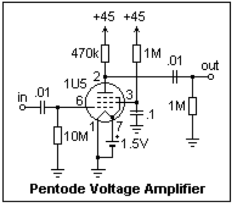
If a crystal ear phone is used or the diode detector is followed by an amplifier (generally of high input impedance) one has to design for maximum voltage at the detector output. Here, we rather have to deliver a maximum of power to the phones. Hence the impedance of the phones (or the speaker) as the AF load should have such a value that a maximum of AF power is transferred to it. The AF source resistance RG is at low RF levels (square-law detection) approximately given by the reciprocal of the slope of the diode characteristic at the operating point. At higher RF levels (linear peak detection) it is determined by the current spikes flowing through the diode. In so far, RG nearly equals the diode resistances as shown in Figs. 5. The tuned circuit presents an AF short.

I determined the equivalent circuit of a pair of high-impedance Telefunken phones (4 k ohms at DC) at 1 kHz by using a measuring bridge and obtained the quantities given in Fig. 2. REA is caused by the electro-acoustical transducing process. The AF source has to provide the real power for REA as well as, necessarily, for the DC coil resistance, and foremost the reactive power for the phone coils (2.5 H) that are to move the membranes. In order to obtain the maximum of power transfer the magnitude (amount) of the overall phones´ impedance ZAF (16 k ohms for my phones) must match the AF source. Again I preferred to experimentally find the optimum AF load: I connected in turn 14 phones and speakers of different impedance to the set, partly connecting two of them in series or parallel, which in total provided 20 load impedance values between 80 ohms and 75 k ohms in magnitude. From the AF voltage measured across these load impedances I determined the AF power. The coupling to the RF signal generator was readjusted to retain RF matching each time the AF load was changed. Fig. 6 shows the obtained results when using a) a diode 1SS16 at low RF power (1 µW) and b) with a 1N914 at higher power (1 mW). The optimum AF load impedance turned out to be, resp., 1.2 and 3 k ohms. In order to simplify matters the diode was in this experiment fixed to the 1/3 tap at the tuned circuit. This meant a compromise as regards matching and generally did not produce quite the maximum of achievable AF power. The dashed curves of higher AF power in Fig. 6 were obtained when the diode was connected to the top of the tuning coil (as discussed above).



(Fig. 6: measured AF power versus AF load impedance.)

In order to present my measurement results in a more general form, Fig. 7 shows the AF power obtained as a function of the AF impedance now divided by the respective occurring source (= diode) resistance. The curves indicate that the maximum is reached when ZAF has a value of 50 to 70 percent of the diode resistance. The simplifications introduced above, like choosing the fixed 1/3 tap, are probably the reason for not reaching a higher percentage. But we can say to be roughly correct with our predictions. - Sometimes it is suggested to match just available phones (speaker) to the diode by using a suitable transformer. I found this only helpful if the mismatch was extremely high. In the other cases the winding and iron losses of the transformer, as well as the inductive shunt, tend to

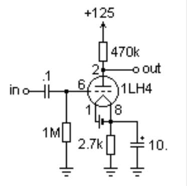


Pentode Voltage Amplifier

A pentode voltage amplifier with a gain of about -33 is shown at the right, using a 1U5, a sharp-cutoff pentode which comes in a 7-pin miniature package. Note the polarity of the filament supply, which is important, since it supplies a little grid bias as well. Since the voltages and currents are low, you can use the same 1/4W resistors used with transistors. The capacitors must have an appropriate voltage rating, of course. The 10M resistor is a "grid leak" that will prevent the grid from going positive. It charges on the positive excursions of the grid to provide whatever bias is necessary. The plate current was 61 μA, and the screen grid current was 20 μA. The screen grid potential is above the plate's in this circuit. Pentodes offer the capacity for controlling the plate current through the screen voltage, so that the plate voltage can be what is required. For higher voltages, the screen grid is normally at the same or lower potential as the plate, on the average. The grid voltage cannot be measured accurately with a DMM or scope, since the bias conditions will be disturbed. However, you will find that the amplifier works very well. Measure the gain the usual way, with a function generator and oscilloscope.

Radios for motor cars had 6 V DC available, which was right for 6.3 V heaters, but could not be used for the B supply--even now, 6 V is inconveniently low for transistors. The usual solution was a *vibrator* supply. Contacts on the magnetically-driven vibrator armature converted 6 V DC to alternating

The 1LH4 is a loktal battery triode, which is shown in a voltage amplifier at the left. A similar octal tube is the 1H5-GT, and either will do in this experiment (but the basing is different!). A diode plate is included, connected to pin 4, and using the negative side of the filament as its cathode. The diode is not used in this circuit. The maximum plate voltage is 110V, but this can be exceeded a little in testing. I measured the characteristics for plate voltages of 125V and less, at grid voltages of 0.0, -0.5 and -1.0V (relative to the negative end of the filament). The plate current was always less than 1 mA. My results were $\mu = 62$, $g_m = 340$ μS, and $r_p = 182$kΩ. These values are close to the published values. The characteristics are noticeably curved in this region, so the parameters will vary with plate current. The apparently low value of transconductance is quite reasonable for the small plate currents at which the tube is used.



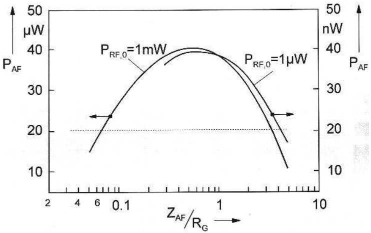
Voltage Amplifier

The amplifier shown gave a voltage gain of G - -40, with an input of 0.4V peak-to-peak. The plate current was about 100 µA, which made the plate voltage 77V and the grid bias -0.26V. The bandwidth of the amplifier was quite good, roughly from 10Hz to 50kHz. It should be noted that the total power drain of this circuit is no more than 83 mW, of which most is the filament power. This is very economical for a normal-sized tube. The tube remains quite cool in service, incidentally.

---

dissipate more AF power than is gained by providing the right transformation ratio. One also has to consider that the human ear cannot register small changes in acoustical power. Alterations like those shown above the dashed line in Fig. 7 will hardly be noticed by the ear. Thus, it seems that the exact value of the AF load impedance is not of paramount importance as regards noticeable output power. But the general principle holds that a number of small improvements in matching, each of which will not produce any audible effect for itself, might in sum indeed be noticed by the ear.

So it turns out as an interesting and important feature that a high-impedance AF load, which is associated with a high DC resistance, will produce a high diode resistance (= AF source resistance), and vice versa. This means that the circuit has a self-optimizing tendency towards the matched condition. Regarding RF selectivity of the set, as another important quantity, a high AF impedance - leading to a high diode resistance - is of advantage. But the influence of the AF impedance in this respect is not particularly pronounced. I measured an increase in -3db RF bandwidth by a factor of 2.5 when the AF load was decreased from 100 k ohms. At 720 kHz (local station) this bandwidth was 20 kHz in my set, which yields a total loaded Q factor of 36 - leaving room for improvement (see Secs. 2 & 3).



(Fig. 7: Measured AF power versus AF load impedance normalized to AF source resistance.)

7. Computer Simulation of Crystal-Set Behaviour

As a summarising investigation I simulated the overall performance of the circuit shown in Fig. 2, using the analysis program SPICE. An RF frequency of 1 MHz, an AF of 1 kHz, and a modulation factor of m=0.4 were assumed. The tap on the coil L2 was held fixed at 1/3 of the windings from earth. The I(V) equation given in Sec. 4 served to describe the diode behaviour.

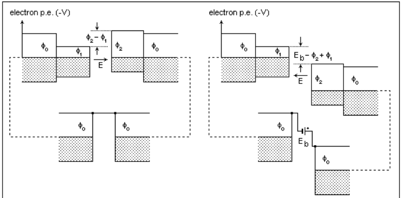
---

because of space-charge effects. When you measure the V-I characteristic of a diode, there appears to be a small positive plate voltage when the measured voltage is zero, and a little current flows. The reason is that the electrons are emitted with some kinetic energy, and a negative space charge is created around the cathode. The actual emission to the anode comes from the minimum of this potential well, which is several volts negative, and so the plate may be slightly more positive than this minimum, in spite of contact potentials.

Battery Tubes

In the early days, nearly all radios (and other electronic apparatus) were powered by batteries, usually primary cells. With the rise of central power distribution, apparatus could be powered (and storage batteries charged) from the AC line, which was a practically unlimited, cheap source so far as radios were concerned. Transformers made high-voltage power supplies easy to build. Low-voltage filaments were largely replaced by 6.3V heaters and unipotential cathodes since power was now cheap. However, there still remained a demand for portable radios beyond the reach of power lines, and these were necessarily powered from batteries. The emphasis here had to be on small power drain, since battery power is expensive. Typical batteries were 1.5V and 3.0 V for filaments ("A" batteries), and 45V or 90V for plate supplies ("B" batteries), both the usual Leclanche "dry" cells. Filaments were generally used, because of their much greater efficiency in mA per watt. Typical battery tubes had filaments taking only 50 mA at 1.4V, only 70 mW. Plate currents were not high, since a few mA would be quite sufficient. For experiments with battery tubes, a D cell in a holder is an adequate filament supply, good for about 100 hours of service. Even an AA cell will do for experiments.

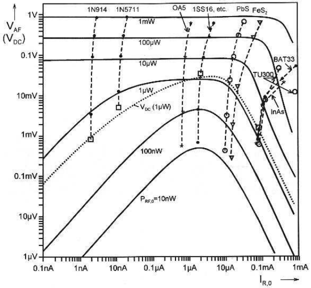
What happens in a vacuum tube is illustrated in the figure below. Suppose metal 1 is the cathode and metal 2 is the anode or grid, and the connections are made by a third metal 0 (there could be several such metals, but they all will act like metal 0). At the left, metals 1 and 2 are connected by a wire of metal 0. If metal 0 includes a DMM, it would show 0 V and, of course, no current would flow. However, the Fermi levels of all three metals must line up for equilibrium, making a level surface on which the electrons will not tend to roll one way or the other. It is clear that in this state of equilibrium, the surfaces of metals 1 and 2 will not be at the same electrostatic potential. An oxide-coated cathode has a work function of about 1.0 V, while a nickel plate or grid has a work function of about 5.0 V. When the Fermi levels align, the cathode is 4.0 V positive with respect to the other electrode.



Effects of Contact Potential

At the right, we have connected a source of emf E_b into conductor 0. A source of emf maintains a difference in the Fermi levels equal to its voltage. With the polarity shown, the cathode 1 has now become negative with respect to the anode 2, by an amount equal to the applied voltage less the difference in work functions. If the device is a thermionic diode, current can now flow from cathode to anode. The actual plate voltage is about 4 V less than the meter says, because of the contact potential. In practice, things are a bit more complicated,

---



(Fig. 8: Simulated AF voltage across high impedance phones reverse saturation current of diode with available RF power as parameter (m=0.4). Measured values for various diodes included.)

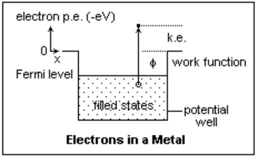
The simulation results are presented in Fig. 8, which shows the AF voltage VAF AF obtained across phones of 16 k ohms AF impedance (4 k ohms DC) as a function of the diode reverse saturation current IR,O. Parameter is the available RF power at the tuned circuit, ranging from 10 nW (lowest sensible level; see Sec. 1) to 1 mW (about local-station level). Measured values pertaining to various diodes are entered for comparison. These measurement values lie in part slightly below, partly somewhat above the simulated curves, but agree in general. In practical diodes, particularly Schottky diodes, the effective reverse current increases noticeably with reverse voltage (i.e. with increased RF power). This had to be considered when inserting the measured values in Fig. 8, and accounts for the slight bending of the vertical lines to the right. The dotted curve in Fig. 8 shows the simulated DC voltage across the phones for 1 µW of RF power.

The simulated curves for VAF drop at the right side for diodes with high IR,O because of the adverse effect of reverse current as mentioned in Sec. 4. The decrease at the left of Fig. 8 for low RF powers results from the high turn-on voltage shown by diodes having a low IR,O. In these cases the associated smaller RF voltages increasingly fail to reach the turn-on of the diodes. The curves make clear how important it is to choose a diode which has the right value of reverse current. A definite maximum in sensitivity, especially pronounced at low RF powers, is found for diodes having a reverse saturation current of a few µA. Particularly the 1SS16 diode class is in this range, but also the OA5 and 1N34 perform not too badly, and good specimen of galena (PbS) crystals behave still satisfactorily. Hence this result is quite in agreement with what we already have found in Sec. 4. - When the AF voltages in Fig. 8 are used for calculating the AF power, the AF/RF detection efficiency can be worked out. It is found that the efficiency drops drastically for low RF levels, with one per mille being reached at 10 nW of RF. This agrees with the observations described in Sec. 1.

In the simulation the reverse breakdown voltage, at which in practical diodes the current starts to rise rapidly, was not included. For 1 mW, the highest RF power considered, the diode resistances have dropped to around 3 k ohms (Fig. 5a), calling for a low tap position on the coil. There the RF voltage is relatively low. My local station, with 3 mW of RF, produces 2.4 V (i.e. a peak-to-peak value of 6.7 V) at the required tap point, so that the negative peak only just reaches the breakdown voltage of -6 V for a 1SS16. In consequence, reverse breakdown seems not to be a particular limiting factor, even if the voltage across the tuned circuit might be somewhat

---

you measure with a DMM are not the actual voltages between electrodes, as seen by the free electrons, but differ by up to a few volts from the true potential differences.

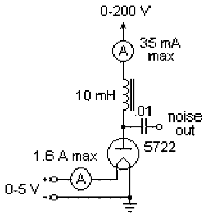


Electrons in a Metal

To understand this, let's review electrons in metals. One or more of the outer electrons of each metal atom is free to wander in the field of the ion cores, effectively binding the metal together. The positive ions create a potential well, as shown in the figure, and the electrons occupy the states of lowest energy. Note that electron energy increases upwards; since electrons are negatively charged, this means that voltage gets more negative upwards. There are not many more states than electrons, so they fill up the states up to some energy called the Fermi energy at 0 K. At ordinary temperatures, there is little difference, since the thermal energy is small compared to the kinetic energy of the electrons near the Fermi level.

If an electron is given enough energy, by thermal agitation or absorption of light, it may be separated completely from the metal and wander freely. The amount of energy necessary to just get outside is called the *work function*. Anything more goes into kinetic energy of the electron. The free electron can now be accelerated or decelerated by electric fields outside the metal in space. Work functions measured by thermionic, photoelectric and contact potential measurements agree roughly, but they depend sensitively on the surface preparation.

increases very rapidly beyond this point. The filament glows brilliantly, like an incandescent lamp, since its operating temperature is about 2400K, not the 900K of an oxide-coated filament. The filament current should not be allowed to exceed 1.6 A. If the power supply has current limiting, it can be useful here. By setting the plate voltage at near 200 V, you can see the saturation current as a function of filament current.



Testing the 5722

For two or more reasonable values of the saturation current, say 5 mA, 12 mA and 20 mA, record the current as a function of plate voltage and plot your results. For I_f = 1.5 A, the plate current saturated for about 50 V on the plate, approaching a value of about 12 mA. It is easy to find out what plate voltage to use to ensure saturation when making shot noise in this way. It is very difficult to make noise measurements in the usual breadboarding environment. I thought it just possible to have seen some on my 100 MHz scope with a plate current of 20 mA, without amplification. See the page on Noise for more discussion of noise measurements.

Contact Potential Effects

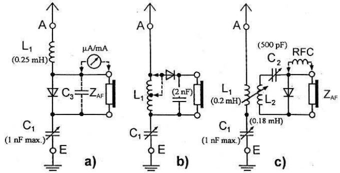
This is a good place to mention contact potentials, since you will probably run into their effects when experimenting with low-voltage tubes. Because of contact potentials, the voltages

---

higher in case there is a better Q factor. Assuming a constant available RF power, the RF voltage is proportional to the square root of the Q (resonance resistance). The low-barrier silicon Schottky diodes, which show a reverse breakdown in the range of -5 to -8 V, are thus well suited for use from the lowest to the highest levels of RF power generally occurring in crystal sets.

8. Some Remarks on Series-Tuned Circuits

Historically the first crystal sets, in the pre-broadcasting days, were of the kind shown in Fig. 9a. There the values of L1 and C2 pertain to my particular antenna/earth situation. For maximum power transfer in the circuit of Fig. 9a the combination of crystal plus load in parallel should match the impedance of the antenna source. In the latter the earth resistance represents the main resistive part which in the then primarily commercial stations had values of only 10 to 50 ohms. On the other hand, the crystal-diode resistances were around a few k ohms so that a considerable mismatch existed. For this reason one soon changed to the arrangement of Fig. 9b with diode and load now in series, and with the possibility to match the diode branch to the antenna by choosing the right tap on the coil L1. To increase the selectivity of the set a second tuned circuit was eventually introduced, as e.g. shown by Fig. 2.



(Fig 9: Series-tuned circuits: a) Diode directly in tuned antenna circuit, b) Diode across tuning inductance (preferably tapped), c) Diode in separate series-tuned circuit, coupled to the series-tuned antenna/earth circuit.)

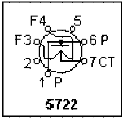
Using modern low turn-on diodes (1SS16 etc., Sec. 4) and having in general a higher earth resistance than in commercial stations, the circuit of Fig. 9a is however quite effective. Possibly paralleling of diodes is of advantage, depending on the actual source and load resistances. With two 1SS16 and employing a moving-coil speaker via a suitable transformer as the load I obtained an AF power of 180 µW from my local station. With ten 1SS16 and two moving coils of 16- ohms speakers in series as load, the obtained AF power of 210 µW approached the maximum possible after Sec. 1. Ideally the diode resistance should, in my case, about equal the 210 ohms of the antenna source (Fig. 1). Reverse diode current is not harmful, nor a possibly low reverse breakdown voltage. We have here a “current-controlled” case where voltages across the diode remain low with associated high currents, a few tens of a mV and some mA when I used the ten diodes. In contrast, voltage control is - more or less - experienced when parallel-tuned circuits are employed where high(er) voltages and low(er) currents exist. A set according to Fig. 9a, then, is a most simple hook-up for effectively receiving the nearest station. Substantially higher selectivity, approaching that of the set of Fig. 2, is offered by the arrangement with two series-tuned circuits shown in Fig. 9c. Since there any resistance (loss) in the circuit made up by L2 and C2 should be kept low for achieving a high Q factor, the diode(s) - preferably paralleled again - and the phones/speaker should be of low impedance. The RF choke might help to improve performance. The diodes found in the left of Fig. 4, particularly the backward diode TU300 (which is of little use on parallel-tuned circuits), operate excellently in the arrangement of Fig. 9c.

---

some surprise, that this correlated successive electrons so that they were emitted regularly to maintain a constant current, and therefore the shot effect was nearly completely eliminated. That is, a normal diode has no shot effect noise in its plate current.

The noise diode is designed so that at reasonable plate voltages, all electrons emitted by the filament are immediately drawn to the plate without forming much of a space charge. Since the electrons are emitted randomly, the anode current will show the full shot effect noise. This is done by purposely making the filament to have low emission. To do this, a tungsten filament is used. Noise diodes give us the opportunity to observe a tungsten filament, as well as temperature saturation.

An available noise diode is the 5722, whose basing is shown at the right. The 7-pin miniature tube was made as late as 1977, and now costs about $14, which is probably not much more than when it was new. The maximum plate voltage is given as 200 V, and the maximum plate current as 35 mA, so apparently the plate can dissipate 7 W. The plate has wings that make a good dissipation probable.



A circuit for testing the 5722 is shown at the left. Note that an RF choke is put in the plate lead to act as a load for the current fluctuations. This choke should be rated for the plate current employed. I connected a variable DC supply to the filament as shown, to pins 3 and 4, leaving the center tap alone. This supply should be rated at 2 A or more. Increase the filament voltage gradually, looking for the glow. There will be no plate current until the filament current reaches about 1.3 A, but it

As an example of the small signal diodes that are often combined with a triode or pentode in the same envelope, and share the same cathode, the 6AV6 or 6AT6 furnish good examples. The 6AV6 has its heater at pins 3-4, cathode at pin 2, and the signal diode plates at pins 5 and 6. The maximum current for each diode is 1 mA. I connected the two plates together for measurement, and took the current up to 3 mA, for which a plate voltage of 6.4 V was required. The curve of I against $V^{1.5}$ sagged a little at low currents, but the upper part was quite linear, showing a perveance of 0.085 mA/$V^{1.5}$ for one plate. The incremental resistance was 4.55kΩ, and V/I was 5.05kΩ at 1 mA. The current for one plate obeyed the formula $I = 0.15 + 0.085V^{1.5}$ mA. In this tube (and similar ones) the plates are flat, one on each side of the cathode.

The 1A3 seems to be the smallest signal diode of all. It was designed for portable measuring apparatus. The heater takes 0.15A at 1.4V (a D cell), connected to pins 1 and 7 of the 7-pin miniature envelope. The cathode is at pin 3, the anode at pins 2 and 6. The peak inverse voltage is 330V max., the maximum plate current 5 mA, and the average plate current 0.5 mA DC. Maximum heater-cathode potential is 140V. The anode is only a few millimeters high; most of the envelope contains only vacuum. The measured perveance was 0.075 mA/$V^{1.5}$.

The Noise Diode

A special kind of diode should be mentioned here, because experiments with it are quite interesting. It is the *noise diode*, intended for the specific purpose of producing wide-band RF noise through the *shot effect*. Shot effect noise is fluctuations in the anode current due to the random collection of electrons. We have already mentioned that the anode current is controlled by the space charge around the filament. It was discovered, to

Modern 8/16- ohms headphones or, for stronger stations, directly the moving coil of a speaker are effective AF loads. - Backward diodes, being scarce these days, are tunnel diodes which have the typical current hump reduced to a flat region at about 200 µA height. The I(V) curve of the TU300 shown in Fig. 4 has in reality reversed polarity. For reasons of comparison with the other diodes the polarity was changed in the graph. Other BWD types are: AEY17 /29, 1N3539 /3543, TU1B.

In conclusion, the investigations sketched here have certainly enlarged my knowledge on crystal-set design, with the identification of the “best diode” and noticing the tendency of self-optimization which makes the set a sort of good-natured device. Other rewarding topics could not be covered, as there are, for example, more complex circuits for increased selectivity and for DX. Also short-wave crystal sets are fascinating since they provide DX from all over the world with simple designs.

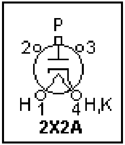
Loktal equivalent to the types 80 or 5Y3 that are now much more expensive.



An excellent diode for observing the Langmuir-Child law is the 2X2A. This tube has a 4-pin base like the 82 phanotron discussed below, and the large, bell-like anode is brought out to a cap at the top of the ST envelope. The oxide-coated cathode thimble is easily seen. The heater takes 2.5V at 1.75A, so it can use the same transformer as the type 82. The rated DC current is 7.5 mA, and the maximum voltage is 4500V. A plate voltage of about 60V is needed to reach 7.5 mA plate current, so measurements can be made over a wide range of voltages. Plot your results as $I^{2/3}$ vs. V. A straight line will be found, that intercepts the V axis at -1.2V. The perveance of the 2X2 is found to be 0.0165 $mA/V^{3/2}$. The unusually low value is due to the large cathode-anode spacing.

The 6V3-A is a strange miniature tube with a cap on top that is the cathode connection. Its heater, connected to pins 4 and 5 of the 9-pin miniature base, takes 1.75 A at 6.3 V. The plate is connected to pins 2, 7 and 9. This tube is designed for the rugged service of a television *damper diode*. During horizontal retrace, the damper diode conducts, charging the boost capacitor while absorbing the large inductive kick. The peak inverse voltage is 6000 V, the peak current 800 mA, and the average current 135 mA. The large-diameter cathode tube and long plate imply a large perveance, which, in fact, is about 2.3 $mA/V^{1.5}$. This tube happens to be very cheap, but would serve as an excellent half-wave rectifier for practically any purpose. There are other damper diodes, such as the 6W4 and the 6AX4GT (perveance 1.42), that would have similar characteristics.

The 6H6 is an octal dual signal diode like the 6AL5, in a unique small metal envelope. The heater is connected to pins 2-7, the cathodes to 4 and 8, the plates to 3 and 5. 3 and 4 are one diode, 8 and 5 the other, and completely independent. It can be used for any reasonable service, such as AM detection, as a full-wave rectifier, or as a voltage doubler, so long as the current per plate is 8 mA or lower, and inverse voltages do not exceed 420 V. The voltage between heater and cathodes should not exceed 330 V. Measure the plate current as a function of the plate voltage up to 10 mA (the plate voltage will be about 7 V), and plot the current against the 3/2 power of the voltage. I obtained a rather straight line, showing agreement with Langmuir-Child, with a permeance of 0.5 $mA/V^{1.5}$. At 8 mA, the incremental resistance was 590Ω, and V/I = 785Ω. The 12H6 and 7H6 are similar tubes with different heater ratings and basing.

The 7Y4 is a typical small full-wave rectifier with an indirectly-heated cathode, like the more common 6X4 (miniature) and 6X5 (octal). This "Loktal" tube is inexpensive. Many of the common rectifier diodes are rather costly, for the curious reasons associated with the current tube market. The heater, taking 6.3V at 0.5A, is connected to pins 1-8 (as with all Loktal tubes). The cathode is pin 7, and the plates are pins 3 and 6. The peak inverse voltage is 1250 V, the peak current 180 mA, and the average dc current 70 mA. The heater-cathode voltage should not exceed 450 V. Measure the plate voltage for currents up to, say, 50 mA, and plot the results as for the 6H6. Again, we find a straight line and a perveance of 0.58 $mA/V^{1.5}$. Note that the plate voltage varies considerably as the current changes, from 4 V at 7 mA, to 16 V at 40 mA. Compare these voltages with those for a mercury-vapor *phanotron* as discussed in the next section. The 7Z4 is a somewhat larger full-wave rectifier (with perveance 0.40), the

Diode Characteristics

by Kenneth A. Kuhn

Oct. 3, 2007, rev. Sept. 3, 2009, draft –more to come

Introduction

This paper examines various electrical characteristics of a typical silicon junction diode. Useful mathematical relations are shown and illustrated with plots.

All of the plots are based on a typical sample of a very common small signal diode, the 1N4148 using a spreadsheet, diode_plots.xls, written by the author and posted on his web site: http://www.kennethkuhn.com . Because parameters vary from diode to diode, these plots should be interpreted as representative rather than absolute. Variations from diode to diode would typically be in the plus or minus several percent. To illustrate temperature effects, several of the plots are created using three temperatures: the high temperature is 100 C, the medium temperature is 25 C, and the low temperature is 0 C.

Forward current versus voltage

The standard equation for current through a diode is:

$I = IS * (\exp(V/(n*k*T/q)) - 1)$ Eq. 1

Where:
I is the current through the diode
IS is the reverse saturation current
V is the voltage across the diode (can be positive or negative)

n is a junction constant (typically around 2 for diodes, 1 for transistors)
k is Boltzmann's constant, 1.38E-23 Joules/Kelvin
T is temperature in Kelvins
q is the magnitude of an electron charge, 1.609E-19 coulombs

Looking at Equation 1 it would appear that the current should decrease as the temperature increases. The exact opposite is what really occurs. The reverse saturation current, IS, is a strong positive function of temperature as discussed below. The increase in IS with temperature more than offsets the effect of T in the exponential above.

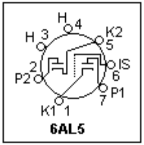
The junction constant, n, is typically a constant at low currents and varies as the current becomes significant and may also vary somewhat with temperature. For this discussion, n will be taken as constant.

The sub-expression, kT/q, has units of voltage and is referred to as the thermal voltage and is typically around 26 millivolts at room temperature.

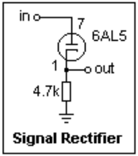
VT = k*T/q Eq. 2

Figure 1 shows a plot of Equation 1 for three temperatures. The strong temperature dependence can be clearly seen. There is a very important thing to note about the plot in Figure 1 –it is not possible to directly obtain the plot by applying a voltage and measuring the resulting current. Doing that will quickly destroy the diode because of a condition known as thermal run-away. Any power applied will heat the diode which in turn will result in the current increasing thus further heating the diode because of the negative temperature coefficient. This can be easily seen in Figure 1. The only way to collect the data for the plot is to apply a current and measure the resulting voltage

---



The 6AL5 dual diode, whose basing is shown at the right (7-pin miniature socket), is a typical signal diode. IS is an internal shield between the diodes. The two diodes and the shield are easily seen through the glass envelope, and you should notice how close the plates are to the cathodes. The close spacing means a large perveance, so only small plate voltages are required. Don't connect this tube directly across high voltages! A peak inverse voltage of 330 V can be resisted, and the DC plate current should not exceed 9 mA. Peak currents can go up to 45 mA if necessary, however. I measured the perveance as 2.42 $\text{mA/V}^{1.5}$, for one plate, a large value. The 6AL5 gives 9 mA with a plate voltage of only about 2.5 V! The heater, connected to H-H, pins 3 and 4, takes 0.3 A at 6.3 V.



Try the 6AL5 in the circuit shown at the left, which is a basic signal rectifier with a 4.7k load resistor. Feed it with the signal generator, and compare the output and input with the oscilloscope. Try input peak-to-peak voltages of only 2 V or so. You will notice that there is no "diode drop" with the 6AL5--it acts like a perfect diode, rectifying down to small voltages. We know how to do this with a semiconductor diode and an op-amp, but here it's done quite simply. The 6AL5 has an incremental resistance of only about 237 Ω, and is nearly linear. It is easy to run a plate voltage versus plate current curve with a low-voltage power supply. Keep the load resistor, and subtract the voltages at plate and cathode to find the plate voltage.

Thermionic diodes have now been completely superseded by semiconductor diodes, largely for economic reasons, physical size and the need for a filament supply. A silicon diode capable of carrying 1 A is available for $0.04 or so, and takes up very little room. However, diodes can teach us a lot about thermionic emission and other interesting things. They do work rather well, and it is good to make their acquaintance.

The forward voltage (in the direction of current flow) of a diode is always relatively low, less than 15 V or so. The plate current is roughly proportional to the 3/2 power of the anode-cathode voltage (Langmuir-Child law), and the proportionality factor is called the *perveance*. The perveance depends on the geometry of the tube, increasing with larger area and closer spacing. It's remarkable that most diodes agree with Langmuir-Childs so well, in spite of different geometries. Since the voltages are low, contact potentials may affect your measurements. Contact potentials are discussed below in the section on low-voltage tubes. The easiest way to find the perveance is to plot $I^{2/3}$ against V, and to draw the best straight line. The intercept gives the value of the "true" zero plate voltage, and the slope, raised to the 3/2 power, is the perveance. Perveances range from 0.02 to 2.4 mA/$V^{3/2}$ for a representative assortment of 12 diodes of all types. There is no turn-on voltage drop for a thermionic diode, as there is for a silicon diode. Conduction begins immediately when the plate is positive with respect to the cathode, and stops immediately when the plate goes negative. It is easy to measure the V-I characteristic of a diode with a low-voltage DC supply, a voltmeter and an ammeter. I use a 100Ω resistor in series to make adjustment easier and safer. Thermionic diodes are not as easy to destroy as semiconductor diodes, and will take a good deal of abuse.

---

across the diode. Diodes are current operated devices and should never have a direct voltage applied from a low-impedance source.

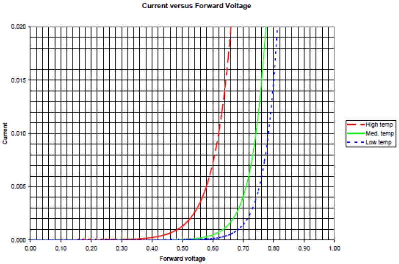


Figure 1: Forward Current versus Forward Voltage

The -1 term in Equation 1 can be omitted when the forward voltage is greater than about 0.1 volts at room temperature. A chart of the approximation and the exact is shown below.

For n = 1, VT = 0.026 volts

	Approximation	Exact	
V	exp(V/(n*VT))	[exp(V/(n*VT)) -1]	error%
0.00	1.00	0.00	infinite
0.02	2.16	1.16	86
0.05	6.84	5.84	17
0.10	46.8	45.8	2.2
0.15	320	319	0.3
0.20	2191	2190	0.05

Logarithmic forward voltage versus current

It is useful to plot the data in Figure 1 with the axis swapped as is done in Figure 2. An interesting observation in Figure 2 is that the forward voltage is a very linear function of the logarithm of the current through the diode. This characteristic is useful in building electronic logarithmic converters. It should also be observed that the slope is a function of temperature and that creates a complication as temperature compensation is required.

Equation 1 can be solved for the forward voltage:

$V = n*VT*\ln[(I / IS) + 1]$ Eq. 3

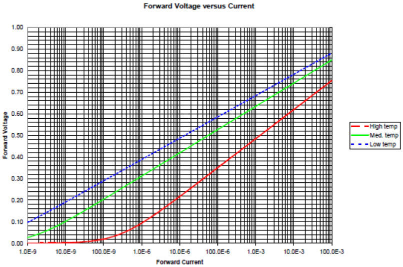

Figure 2: Forward Voltage versus Forward Current

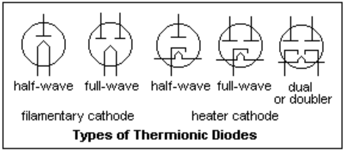
Reverse saturation current

When negative voltages are applied to the diode the current becomes constant at –IS as the exponential term in Equation 1

Diodes

Thermionic diodes, like semiconductor diodes, are divided into *signal* diodes that handle small currents at low voltages, and *rectifier* diodes that handle large currents, often with large inverse voltages. A diode has an electron-emitting cathode and an electron-receiving anode or plate. The arrangments of cathodes and plates in commercial tubes, and what they are called, are shown in the figure. Signal diodes are also often added to a triode or pentode, sharing the same cathode and with one or two plates. Current flows only from plate to cathode, and this unidirectional conduction is the purpose of a diode. Diodes cannot amplify.



Signal diodes always have indirectly-heated cathodes, so they are easy to use. It is only necessary to make sure that the heater-cathode voltage does not exceed specified limits, usually a few hundred volts. Rectifier diodes often have filamentary oxide-coated cathodes, since these cathodes are more efficient when large currents are needed, requiring less power. We are considering only vacuum diodes, *kenotrons*, in this section. Thermionic gas diodes, or *phanotrons*, will be treated below, since they have rather different properties.

Bakelite) to support the contact pins mechanically, taking the strain off the pressed-glass seal, which was made of lead glass. Around 1935, the metal envelope was developed, but there was still a base. The all-glass "miniature" tube was made possible by the "button seal" that supported the contact pins mechanically as well as bringing them through the glass, allowing the base to be eliminated and tube size to be reduced. The insides, or "cage," was the same size as in previous tubes, however. It is supported on its leads, which are welded to the contact pins before the envelope is fused in place and evacuated. The button seal is also used, in a larger form, on tubes designated by GB at the end of the type designation, and by Loktals. The final step in manufacture was "flashing" the getter, usually barium or magnesium, to perfect the vacuum by adsorption of any remaining gases, leaving a shiny coating. This was generally done by heating a loop inductively by RF from outside.

quickly approaches zero. That is why it is referred to as the reverse saturation current. The current is independent of applied voltage once a small voltage magnitude is exceeded. This current is very small and is typically in the low nanoampere region. The reverse saturation current is a strong function of temperature as illustrated in Figure 3. The following equation is a simplified model for the reverse saturation current and provides excellent results in normal operating regions.

IS = IK * exp-Eg/nVT Eq. 4

Where:
IS is the reverse saturation current
IK is a constant derived from n and IS at a known temperature
Eg is the bandgap voltage for silicon (ranges from about 1.20 to 1.28 volts)
n is the junction constant (typically around 2 for diodes, 1 for transistors)
VT is the thermal voltage as previously discussed

The reverse saturation current should not be confused with an imperfection in diodes known as leakage current from a high value shunt resistance across the diode jucntion. Leakage current is often many times larger than IS. Thus, IS can not be directly measured and must be computed using data from the forward bias region (see the section on measuring diode characteristics).

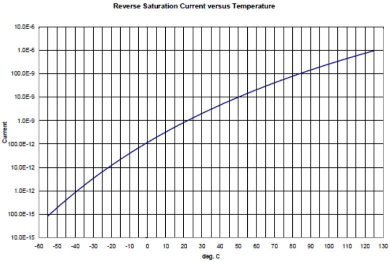


Figure 3: Reverse saturation current, IS, versus Temperature

Near Zero Bias

A theoretical plot of the diode current for the near zero bias condition is shown in Figure 4. Note that once the reverse voltage exceeds about -0.2 volts in magnitude that the reverse current is the value for IS and is independent of reverse voltage –this is why it is referred to as the reverse saturation current. Only the plot for room temperature (25 C) is visible. The low temperature plot is too small to observe on this scale except for the small forward bias region. The high temperature plot is very steep passing through zero volts. This illustrates why it is important to keep diodes cool when reverse current is an issue.

The plot in Figure 4 does not include the effect of leakage shunt resistance across the junction resulting from imperfections in the manufacturing process. This resistance varies from hundreds of millions to tens of billions of ohms. This shunt resistance results in an increasing current with applied reverse voltage and the current can become many

so the locking action guarantees that the tube will stay in the socket in spite of the small pins. The tubes are roughly the same size as an octal GT tube. Most are one size, but a few power tubes have a slightly longer envelope. There are no grid caps on any Loktal tube, and the heater connections are always to pins 1 and 8. Among the thoughtful features of loktal design, the type number appears in a hexagon on the top of the tube where it is visible from above, not on the side as on octal tubes. There is a dimple on the base corresponding to the key of the central pin, making the tube easy to orient for insertion. It seems that a lot of getter was used, so the tops of the envelope appear heavily silvered. The available types are only those used in AM and FM receivers. There are, nevertheless, enough types for a broad variety of experiments, and the prices are not excessive, so you may want to standardize on Loktals. Type numbers beginning with 7 have 6.3 V heaters, while type numbers beginning with 14 have 12.6 V heaters. There are some 7xx and 14xx tubes that are not Loktal, and some tubes that actually take a 7 V heater supply. One loktal rectifier, the 5AZ4 (a 5Y3 equivalent), has a 5 V filament. Loktal tubes designed specifically for battery-powered equipment had 1.4V filaments. The type numbers began with "1L." There were also rectifier and beam power loktals with 35, 50 and 70-volt heaters for AC/DC sets with series heater connections.

A tube designated simply 6N7 will be a metal-envelope octal tube with a 6.3V heater. A 6N7GT will have a cylindrical glass envelope. A 6N7G would have a shouldered glass envelope of the graceful shape designated ST. The electrical characteristics of such tubes were the same, whatever the envelope shape.

A very important part of vacuum-tube technology was bringing the metal leads through the glass envelope. Coefficients of expansion must be exactly matched, and the seal must be strong. Originally, tubes had bases (usually "duodecal" tubes were used in TV sets. Miniature tubes were not miniature, simply tubes with a button seal and all-glass envelope closely fitting a normal-sized cage. Subminiature tubes were actually miniature. Sometimes connections to grid, plate or (rarely) cathode were made to caps at the top of the tubes. In small tubes, these caps have a diameter of 1/4". The pins are numbered consectively clockwise, starting from the left of the index key for the octal, or to the left of the wider space, for the miniature, always looking at the bottom of the tube. This is shown for the octal base at the left. Pin numbers are given in the circuit schematics here. Most sockets have pin numbers marked. You will need to get sockets for the tubes you study, one for each type of socket. Solder wires to the tab at each pin that can be inserted in the solderless breadboard. I use the resistor color code for the pin numbers. A convenient octal socket fixture is available that comes with screw terminals for making connections. It was intended for relays, but is very useful for tube experiments. Heater connections for octal tubes are typically (not always!) to pins 2 and 7, and often to pins 3-4 on 7-pin, or 4-5 on 9-pin, miniature tubes. Sometimes halves of the heater can be connected in series or parallel, for two different voltages. Sockets were originally mounted in holes punched in aluminum chassis, secured by locking rings or by screws and nuts with a mounting plate. The chassis was, not surprisingly, the ground or common.

The "Loktal" tube was an excellent idea that was never universally adopted, mainly because miniature tubes took over in the 1950's. Since loktal was a trade name, RCA used "lock-in" instead, and you sometimes see "loctal." The loktal tube has an 8-pin button-seal (like the seal on miniature and octal GTB tubes). A natural metal base (of some aluminum alloy, apparently) shields the base of the tube and has a central pin with a circumferential locking groove. The pins project only 6 mm, and are 1.4 mm in diameter, much smaller than octal pins,

times IS. The effect of this resistance is most important at low temperatures where IS is very small. At high temperatures the effect of large IS swamps the resistance.

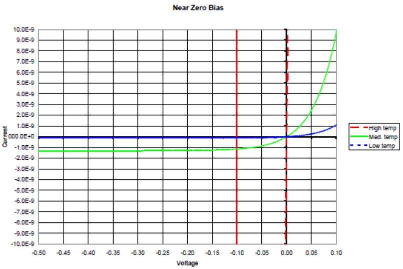

Figure 4: Near Zero Bias

(the vertical red line at -0.1 volts is a Microsoft bug and not part of the actual plot)

The plot in Figure 5 includes the effect of leakage shunt resistance. For this plot the resistance is 100 Mohms which was chosen for illustration and is very low compared to typical values of 1000 Mohms or more.

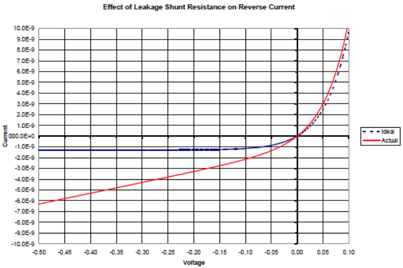

Figure 5: Effect of leakage shunt resistance

Temperature effect on forward voltage
With a constant current, the forward voltage drop of a diode has a very linear negative slope with temperature. The slope is also a function of current which is why constant
current must be used. This characteristic is useful for building electronic thermometers. This characteristic is shown in Figure 6. Note that the slope becomes steeper as the current through the diode is reduced. For practical temperature measurements it is important that the diode not heat with the applied current. The power dissipation should be less than 1 milliwatt. This means that the constant current should be no more than
about 1 milliampere. The plot in Figure 6 is based on Equation 3 but the x-axis is temperature instead.

main B+ supply. This cannot be done, of course, if the B+ voltage is adjusted using a variable transformer.

An all-in-one economical supply for vacuum-tube measurements is shown below. It uses an inexpensive isolation transformer from All Electronics, and can be made for about $30.00. The most expensive single part is the aluminum chassis. The grid potentiometer could be a precision 10-turn pot, but this would be expensive, and an ordinary carbon or plastic potentiometer (1/2 W or better) will be satisfactory. The maximum plate voltage of 120V and maximum plate current of 35 mA is adequate for many measurements. If you use a three-wire line cord, ground the chassis to the green wire. If you use only a two-wire line cord, it is probably better not to ground the chassis.

Octal Socket

Vacuum tubes come with metal or glass envelopes, and in latter days with either the familiar octal arrangment of 8 pins, or as miniature glass tubes with 7 or 9 pins. There were earlier bases with four, five or six pins. Later, 12-pin miniature "compactron" or

The RC ripple filter is worth the expense. Waveforms are shown at the left. The waveform at node "a" is the familiar one for a "tank" capacitor, and the ripple is fairly large. Since the impedance of a 100 μF capacitor is only 26Ω at 60 Hz, the ripple is reduced by a factor of almost 25. At 300V output and a load of 12 mA, the ripple is less than 0.1V, a very satisfactory result. Note that all that is left in the ripple is the 60 Hz component. The filter would work even better on a full-wave rectifier, but here it is very satisfactory, better and more economical than larger capacitors. Of course, a filter choke could be used for an even better result and less voltage drop, but this would double the cost of the supply.

You will also need a heater transformer, which can be quite small if supplying only one tube that requires 0.3A. The transformer can be put in a box with an on-off switch and convenient terminals. Ground the heater supply (at a center tap if one is provided) to the B+ ground, to avoid excess voltages between heater and cathode. If you have a 12.6V CT (center-tapped) secondary, you can supply both 6.3 and 12.6 V heaters. Many 12.6V miniature tubes can also be connected for 6.3V. Tubes whose designations begin with "1" have filaments that can be supplied from a single D cell. Obtain a holder for the cell so connections are easy. 6.3 V was chosen to be compatible with 6 V car batteries, but the supply is usually AC. Many rectifier diodes use a 5 V filament or heater supply, apparently for historical reasons.

A "C" supply, for the grid bias in measuring characteristics, can be any isolated low-voltage supply of say, 15V, and a potentiometer can be used to pick off a variable voltage, since little current is involved. A separate high-voltage supply for screen grids may also be convenient, though it is easy to pick off the necessary voltages with a Zener or a VR tube from the

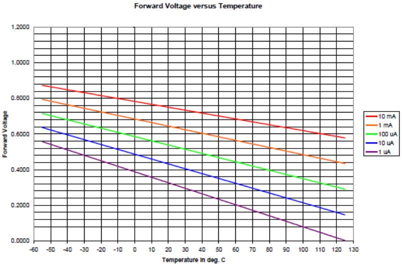

Figure 6: Forward Voltage versus Temperature

Temperature slope of forward voltage

The slope of the forward voltage versus temperature curve varies with the magnitude of the constant current as shown in Figure 7. This plot is made by taking the derivative of Equation 3 with respect to current.

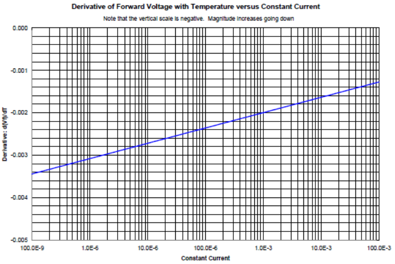

Figure 7: Derivative of Forward Voltage with Temperature versus Constant Current

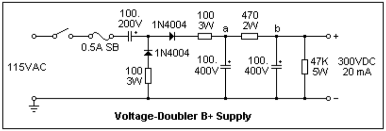
Forward dynamic resistance

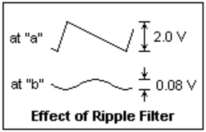
The operating point on Figure 1 represents a conductance (or its reciprocal function, resistance) for small signals (less than about 20 mVpp). The resistance is the reciprocal of the slope of the line through the operating point. This makes it possible to have an electrically variable resistor –the resistance is inversely proportional to the current. Electronically variable resistors are useful for building multipliers and gain control circuits. By taking the reciprocal of the derivative of Equation 1 (leaving off the -1 term) we have the forward dynamic resistance.

rd = n * VT / I Eq. 5

Observe that this resistance is a strong function of temperature. A plot of Equation 5 is shown in Figure 8.



An idea for an inexpensive B+ supply is shown at the right. The greatest expense is for the capacitors, which will cost about $15. It is based on a half-wave voltage doubler, and gives 300V for a 115V rms input. It cannot supply large currents, but is perfectly satisfactory for anything but power amplifiers. If supplied from a variable transformer, it becomes a variable supply for all voltages from 0 to 300. Note very carefully that one side of the supply is connected to the AC line, and this must be the grounded side, for your safety, and to avoid ground loops. You cannot ground the positive terminal of this supply to get a negative voltage supply (for use as a C supply, for instance). An isolation transformer, if you have one, would eliminate this hazard. If you don't have an isolation transformer, use a polarized plug to guarantee that the white wire is connected to the circuit ground. If you have a good ground, consider the old trick of connecting only one wire in the power cord, and using the ground to complete the circuit. It is best to observe the power ratings of the resistors and the voltage ratings of the capacitors. This circuit has been tested, except for the fuse. If the 0.5A slow-blow fuse fails, try a 1.0A. This fuse is to turn things off if a capacitor fails; nothing valuable is protected here, but it saves mess.



directly, because of the ground hazard. A variable transformer (Variac) is an *autotransformer* that does not isolate the output from the power line ground. I earnestly recommend that you do not work on AC circuits without isolating them from the service ground. The 110/220 adapters commonly available in 50W and 300W sizes, used for shavers and other small loads, should not be used, since they are autotransformers and do not provide isolation. They are, in fact, quite dangerous things, and should be used with great care. The supply was built in a 5" x 7" x 3" aluminum box, with an octal socket for the VR tube on top. The socket can be left vacant when the fixed voltage output is not required.

The voltage regulator requires a certain minimum current (about 5 mA) to function properly. If you are only drawing a few milliamperes from the supply, connect a 12k bleeder resistor across the output. Otherwise, the regulator will not adjust down to the lower voltages. Or, 220Ω and 10k fixed resistors, and a 15k pot, could be used at the voltage regulator, which would draw the necessary minimum current. The VR tube can be replaced by a high-voltage Zener diode.

A 25W isolation transformer is available at the date of writing from All Electronics (See the Your Laboratory page for a link) for $4.50. This transformer is surplus from the Power One firm, and is an excellent value. Solder a jumper between tabs 1 and 3, and another between tabs 2 and 4. The 120V input is connected between 1-3 and 2-4. The output tabs are marked B. This transformer would work well in the circuit above, or it could be put in a box and wired with line cord and output receptacle as a general isolation transformer. It should supply 200 mA without trouble, ample for our purposes.

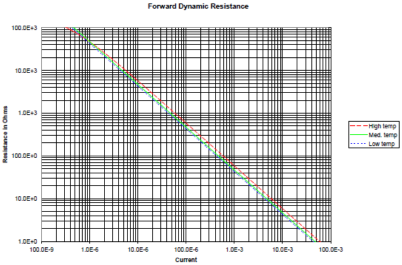


Figure 8: Forward Dynamic Resistance versus Current

Bulk Resistance

All diodes have a bulk resistance, Rb, that is in series with the diode. This resistance is typically very small (typically around 1 ohm or less) and its effects are insignificant at lower currents. At higher currents the effect is to reduce the voltage across the junction by the current multiplied by the resistance. This results in the steep theoretical exponential current versus voltage curve transforming into a linear slope. Equation 6 is Equation 1 with the effect of Rb included. Equation 6 (which omits the -1 term as that is not applicable for the higher diode currents) does not have a closed form solution as there is no known way to manipulate the equation such that either I or V is not involved with either a logarithmic or exponential term. Numerical solutions are the only way to solve Equation 6. Newton’s method was used to generate Figure 9.

$I = IS * \exp((V-I*Rb)/(n*k*T/q))$ Eq. 6

Figure 9 is a plot of Equation 6 and shows the effect of a 1 ohm bulk resistance for the room temperature case of the diode. Notice how the current is significantly less than theoretical for higher diode voltages. Note that the slope is nearly linear.

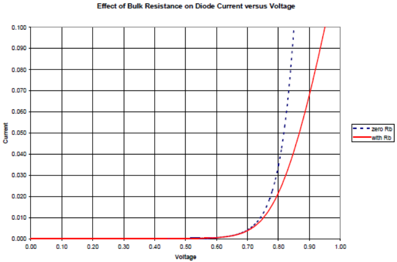

Figure 9: Effect of bulk series resistance

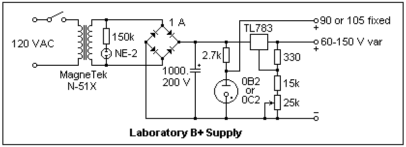
Sensitivity to light

The PN junction will respond to light –particularly longer wavelengths such as red and infrared. This feature can be a problem for diodes in transparent cases such as the 1N4148. The effect of light is to significantly increase the reverse conduction. A voltage can appear across the diode in response to light in high impedance circuits. This can be observed by connecting a diode (in a transparent case such as a 1N4148) to a DVM on the 2 volt scale and varying the applied light. In situations where light sensitivity could be a problem it is common to enclose a transparent diode in an opaque sleeve.

precautions and normal care, you will be fine. The solderless breadboard, DMM and oscilloscope can handle these voltages quite well. All the usual resistors and potentiometers are not afraid of 150V, so long as power ratings are observed. 1W and 1/2W resistors may be required in some places. Capacitors must be able to stand the voltages across them; many of those used with transistors will not be adequate. Keep a separate kit of capacitors rated at 100 V and above for this work. High-voltage capacitors are not needed everywhere, only in the plate circuits and for coupling from plate circuits.



The circuit of the laboratory B+ supply that I use for vacuum tubes is shown at the right, and the supply itself is shown in the photograph below. It provides a regulated variable 60-150 V output, and a regulated fixed voltage output (for screen supply) created by a VR tube. VR tubes can be exchanged for different voltages. The MagneTek N-51X 115 V-115 V isolation transformer is available from Antique Electronics (see references), and a cheaper one from All Electronics. The transformer secondary has a DC resistance of 22Ω, which limits the surge current satisfactorily without having to add a series resistor. By no means eliminate the isolation transformer and use the 120 V household supply

were manufactured for voltages of 75, 90, 105 and 150 that were used like Zener diodes, handling from 5 to 40 mA. There is more information on glow discharges in Relaxation Oscillators, and on Zeners in Voltage Regulators. VR tubes are treated here because of their association with vacuum tubes, and the higher voltages involved.

Experiments

Vacuum tubes generally operate at higher voltages than transistor circuits. Like transistors, vacuum tubes are happier at higher voltages, which for receiving-type tubes, typically would be, say, 200 to 250V. It was once quite common to make DC power supplies for such voltages, using a transformer with a center-tapped secondary (say 200-0-200V), and a rectifier with double anodes and a common cathode, feeding a filter consisting of capacitors of 8 or 16 μF, and a choke of 10 H or so. It was not convenient to make a bridge rectifier with vacuum diodes (three separate filament transformers are necessary), so full-wave rectification with a center-tapped secondary was usual. These days it is rather difficult (and expensive) to acquire all these things, with the possible exception of the capacitors, which are now available up to millifarads at voltages up to 450 V.

The voltages normally used with receiving tubes are not high enough to be really dangerous, though a shock will not improve your day. If you are eager for new experiences, I can save you the trouble of finding out by saying that a DC shock is kind of like a hammer blow, not the zap of an AC shock, and does not paralyze, as an AC shock does. Shocks are given by current, not simple contact, so a good and old rule is to work with one hand in your pocket around high voltage. Always turn things off before making any adjustments or changes, of course, and be neat. Avoid touching bare metal. With these

---

There is a special type of diode known as a photodiode which is specifically made for sensing light. The case is transparent and often includes a lens to focus the light on the junction for increased sensitivity. Technically, it is usually infrared emission between around 800 to 1100 nanometers rather than visible light that these diodes are sensitive to. The sensitivity in the visible spectrum is usually poor except for what is known as blueenhanced diodes. These diodes can be operated either in an unbiased voltage mode or a current mode using a fixed bias around 5 volts. The current mode is very linear over a wide range. The current is sensed by a virtual ground electrometer.

Measuring Diode Characteristics

The mathematical model for diode operation can be completed by knowing IS and n. Neither of these are directly measurable but both can be calculated from data obtained by measuring the diode current at two voltages with temperature constant. We start with the following equation that omits the minus one term since our measurements will be at voltage levels high enough so that term is insignificant. Thus we have:

$I = IS * \exp V/(n*VT)$ Eq. 6

Equation 6 can solved for V by

$V = n*VT*\ln(I/IS)$ Eq. 7

$VH = n*VT*[\ln(IH) - \ln(IS)]$ Eq. 8A
$VL = n*VT*[\ln(IL) - \ln(IS)]$ Eq. 8B

Where H refers to the high voltage and high current measurement point and L refers to the low voltage and low current measurement point. These two points should be at currents less than 1 mA so that junction heating is insignificant. Good points to use are nominally 500 uA for the high value and 5 uA for the low value.

Subtracting Eq. 8B from Eq. 8A gives

$(VH - VL) = n*VT*(\ln(IH) - \ln(IL)$ Eq. 9

Eq. 9 can now be solved for n

$$n = \frac{VH - VL}{VT * [\ln(IH) - \ln(IL)]} \quad \text{Eq. 10}$$

As a reality check, n is typically between around 1.6 and 2.0 for diodes and should be very close to 1.0 for transistors. Suspect some error if n is less than 1.0 or greater than about 2.2. The most common type of errors are using an inaccurate temperature or that the high and low measurements were made at different temperatures.

We can now calculate IS for the particular temperature the data was measured at. That temperature, T, must be known and the corresponding value of VT used in the following equation.

$IS = IL * \exp{-VL/(n*VT)}$ Eq. 11

As a reality check, IS should be around 1 nanoampere give or take perhaps a factor of ten for diodes. For transistors, IS will be extremely small –picoamperes or less.

The proof that these two values are correct is that they produce results that agree with measured data over a wide range when the model is plotted. The use of only two points for the calculations makes it extremely important to keep

also acted as an electrostatic shield between control grid and plate, reducing the Miller capacitance to extremely small values, 0.003 pF in the 6SK7. If the screen and suppressor grid are connected to the plate, the pentode operates as a triode.

A very curious and ingenious kind of tube was the *electron-ray* tube, used on receivers to give a visual indication of the accuracy of tuning to a station. Don't confuse it with the *cathode-ray* tube that uses a guided electron beam for oscilloscopes and TV receivers. It showed a luminous disk, with a dark sector. The dark sector was made as small as possible to achieve accurate tuning. It worked from the AGC (automatic gain control) voltage of the receiver. This is a feedback signal that tries to keep the signal amplitude constant at the output of the intermediate frequency amplifiers, increasing the gain for weak signals and decreasing it for strong. It is usually a negative voltage produced by rectifying the IF output. The tube has a thermionic cathode and a conical anode or *target* covered with cathodoluminescent phosphor (like a CRT), which glows from the 3 or 4 mA of plate current that flows when it is across 125V or more (up to 250). Control electrodes, of which there are two on opposite sides of the 6AF6, make two dark sectors that are widest when at 0V, and narrow as the control voltage approaches the target voltage. The control voltage is typically provided by the plate of a triode controlled by the AVC, such that full negative AVC cuts off the triode and makes the sector as small as possible. All this was cheaper and more graphic than a pointer meter.

Another kind of tube that we'll look at here is the glow-tube voltage regulator. The voltage across a glow discharge depends on the gas and the cathode material, and is almost idependent of the current through the discharge in the "normal glow" region, in which the glow does not completely cover the cathode, and expands to accommodate more current. Tubes toward the plate, to suppress the escape of secondary electrons. This is provided by a third grid, the *suppressor grid*, which is usually connected to the cathode. The tube with three grids: control, screen and suppressor, or grids 1, 2 and 3, is called a *pentode*, which turns out to be a superior voltage amplifier, fully equivalent to a transistor. A typical small pentode, the 6SJ7, has a plate resistance of over a megohm, and a transconductance of 1.6 mS.

An ingenious modification of the pentode has electrodes that shape and concentrate the electron beam instead of a suppressor grid, the negative space charge of the electrons doing the same work. These are called *beam power* tubes, and were good for power work, as the name indicates. A typical example, the 6L6, had a transconductance as high as 6.0 mS, and the smaller 6V6 about 4.0 mS. Both types were widely used for high-fidelity audio amplifiers, and tube amplifiers still have proponents. The same tubes were used in small amateur radio transmitters, which shows the versatility of vacuum tubes.

Receiving pentodes were also classified as *sharp cutoff* or *remote cutoff*, an example of designing tubes to fit their applications. A remote cutoff pentode had a grid with variable spacing, so that areas of wider spacing let electrons through when the grid was made more negative, when areas of smaller spacing were cut off. This effectively reduced the transconductance of the tube, decreasing its gain in response to increased negative grid bias, which was used for AGC (automatic gain control) in IF amplifiers. The 6SK7 was a very popular remote cutoff pentode used as an RF and IF amplifier. The 6SJ7, on the other hand, was a *sharp-cutoff* pentode, used as an audio voltage amplifier. The amplification factor has little significance with pentodes, as with transistors, and transconductance is the important parameter. The screen grid

measurement errors small. Much better accuracy is obtained by using a spread of data over a wide operating range (say currents from 10 microamperes to 1 milliampere) and then using linear regression to identify n and IS. That method is straightforward and is not shown here. For single situations one would enter data in a spreadsheet and then manually tweak n and IS in the spreadsheet model to minimize the sum of error^2 between measured diode voltage and the voltage computed from the model.

The model for the complete diode characteristic including the effect of temperature on IS can be determined by substituting the computed values for n and IS from above and the thermal voltage based on the measured temperature into the following equation.

IK = IS * exp(Eg/(n*VT)) Eq. 12

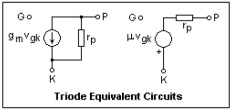
As an example, at 25 C the calculated values for a sample diode was 1.83 for n and 1.3 nanoamperes for IS. Eg was taken to be 1.23 –roughly a middle value. IK was then computed to be 338 amperes. These are the values used to create all the plots in this paper.

More to come …

shall examine these circuits in detail in the experiments, but this provides the background.

In order to provide higher voltage gain, the plate resistance must be reduced somehow. We recall that with a transistor, the analogous collector resistance was very large, and there was no problem with voltage gain. The plate resistance is the result of the effect of plate voltage on the space charge. This effect is not necessary for control, which is provided by the control grid, so what we need is to eliminate the effect of the plate voltage on the space charge. This is done by introducing another grid, the *screen grid* between the control grid and the plate. If this grid is held at a constant potential, the space charge is "screened" from the effects of changes in plate voltage. The screen grid is usually bypassed to ground by a capacitor, whose reactance at the lower corner frequency should be smaller than the resistance connecting the screen grid to B+. Some, but few, electrons are removed by the screen grid, since it is again a coil of fine wire. With this change, the plate characteristics become (nearly) horizontal lines, as for the transistor, and the plate resistance becomes large, approaching a megohm. The resulting tube is called a *screen-grid tetrode*.

Although tetrodes worked as expected, they had a serious defect. It happens that speedy electrons colliding with the plate knock out *secondary* electrons. In a triode, these are rapidly sucked back to the positive plate, and the same happened in a tetrode when the plate potential was higher than the screen grid potential. In normal operation however, especially with large voltage gain, the plate voltage has a large swing, and can become less positive than the screen grid. Now all these secondary electrons (and some of the primary ones, too) are attracted to the screen grid, and there is a definite sag in the characteristic in this region. To prevent this, it is necessary to establish an electric field at the plate that is always directed amplifiers, the allowable plate currents can be quite a bit larger, and hundreds of watts output is possible with relatively small tubes. The interelectrode capacitances of the 6J5 are on the order of 3.4 pF, and are significant at high frequencies.



Triode Equivalent Circuits

The small-signal equivalent circuits for the triode are shown at the right. The Norton source circuit is exactly the one for the FET. In the case of the triode, the plate resistance is always important, and cannot be neglected. The other circuit is just the Thévenin source corresponding to the Norton source. It shows the significance of the amplification factor, and is useful for triodes because of the rather small plate resistance. We did not find the Th%eacute;venin source for transistors very useful, and did not introduce a parameter analagous to the amplification factor for this reason.

It's easy to see that the maximum voltage gain achievable with a triode is μ, if the load resistance is much higher than the plate resistance. The rule we derived for the gain of a transistor amplifier as the ratio of the collector and emitter resistances holds here as well, expressed by $\mu = g_m r_p$. The quantity analogous to r_e is $1/g_m$, which is 333Ω for the 6J5. Mu is a rather modest number, so triodes are not good for high voltage gain. They make very good power amplifiers, however, since large currents can be controlled. Using the Thévenin source, the gain of a usual common-cathode amplifier (analogous to a common-emitter amplifier) is simply a voltage divider problem. There must be a plate resistor in series with the plate, or else the voltage would never change, but it should be as large as possible, and has only a small effect on the gain. We

Chapter 4: p-n Junctions
4.4.4. **I-V characteristics of real p-n diodes**

The forward biased I-V characteristics of real p-n diodes are further affected by high injection and the series resistance of the diode. To illustrate these effects while summarizing the current mechanisms discussed previously we consider the I-V characteristics of a silicon p+-n diode with Nd = 4 x 1014 cm-3, tp = 10 us, and up = 450 cm2/V-s. The I-V characteristics are plotted on a semi-logarithmic scale and four different regions can be distinguished as indicated on Figure 4.4.5. First, there is the ideal diode region where the current increases by one order of magnitude as the voltage is increased by 60 mV. This region is referred to as having an ideality factor, n, of one. This ideality factor is obtained by fitting a section of the curve to the following expression for the current:

$$J = J_s e^{V_a/nV_t} \qquad (4.4.39)$$

The ideality factor can also be obtained from the slope of the curve on a semi-logarithmic scale using:

$$n = \frac{\log(e)}{V_t\,\text{slope}} = \frac{\frac{1}{\text{slope}}}{59.6\,\text{mV/decade}} \qquad (4.4.40)$$

where the slope is in units of V/decade. To the left of the ideal diode region there is the region where the current is dominated by the trap-assisted recombination in the depletion region described in section 4.4.3.2. This part of the curve has an ideality factor of two. To the right of the ideal diode region, the current becomes limited by high injection effects and by the series resistance.

High injection occurs in a forward biased p-n diode when the injected minority carrier density exceeds the doping density. High injection will therefore occur first in the lowest doped region of the diode since that region has the highest minority carrier density.

Using equations (4.4.1) and (4.4.2), one finds that high injection occurs in a p+-n diode for the following applied voltage:

$$V_a = 2V_t \ln \frac{N_d}{n_i} \qquad (4.4.41)$$

or at Va = 0.55 V for the diode of Figure 4.4.5 as can be verified on the figure as the voltage where the ideality factor changes from one to two. For higher forward bias voltages, the current no longer increases exponentially with voltage. Instead, it increases linearly due to the series resistance of the diode. This series resistance can be due to the contact resistance between the metal and the semiconductor, due to the resistivity of the semiconductor or due to the series resistance of the connecting wires. This series resistance increases the external voltage, Va*, relative to the internal voltage, Va, considered so far.

$$V_a^* = V_a + IR_s \qquad (4.4.42)$$

Where I is the diode current and Rs is the series resistance.

These four regions can be observed in most p-n diodes although the high-injection region rarely occurs, as the series resistance tends to limit the current first.

---

varied, the plate current and voltage vary along the load line. The quiescent or operating point can be selected at some point along the DC load line, and so the DC grid bias can be found. This grid bias can be obtained from a C battery or equivalent, or from a cathode resistor, just as an emitter resistor is used with a transistor.

A cathode bias resistor is often bypassed by a capacitor if its negative feedback effect is not desired in dynamic operation. The reactance of the capacitor at the lower corner frequency should be equal to the resistance looking into the cathode (normally $1/g_m$ in parallel with the cathode resistor). The size of the cathode resistor has only a small effect on the size of the bypass capacitor. The capacitor never has a large voltage across it, and can be a low-voltage electrolytic. Only part of the cathode resistor can be bypassed if some feedback is desired.

A typical triode, of which the 6J5 is chosen here as the example, has a $\mu = 20$, $r_p = 6.7$k and $g_m = 3.0$ mS. Of course, the relation $\mu = g_p m_p$ always holds. The value of transconductance may seem small, compared to a transistor, but it should be remembered that it refers to a high-voltage plate circuit, and that the input impedance is infinite, so the power amplification is extremely large. The 6J5 is called a "medium-mu" triode. The similar 6SL7, a "high mu" triode, has $\mu = 70$, $r_p = 44$k and $g_m = 1.6$ mS. The 6SL7 is a *dual* triode, two independent valves sharing the same heater. The dual version of the 6J5 is the 6SN7.

The maximum plate voltage of the 6J5 is 300V, and the maximum plate current is 20 mA. Its maximum *plate dissipation* is 2.5W (product of average plate current and average plate voltage). This gives an idea of the ratings of receiving tubes used as voltage amplifiers. As power characteristics are curved, these quantities vary for different currents and voltages.

What we desire to represent is a function of two independent variables $I_p(V_p,V_g)$, which can be represented as a surface in three dimensions. Our various characteristic curves are orthogonal views along one or another of the axes. There are three such views possible, each directly related to one of the three parameters, of which we generally use only two, the ones mentioned here.

A vacuum tube carrying a current I with a plate voltage V dissipates power VI, just as if it were a resistor. However, the process is different. In a resistor, an electron gives up small amounts of energy to the lattice as it is accelerated and then is scattered. In a vacuum tube, the electron acquires a kinetic energy as it is accelerated, which it gives up all at once when it collides with the plate. It is not really correct to ascribe this to the "plate resistance," as some texts do, which is an incremental ratio. Since the plate is in a vacuum, the resulting heat can only be radiated or conducted down the supports. Much of the radiated heat is infrared, which is absorbed by the glass tube envelope. Note how plates are blackened to raise their emissivity and often provided with fins. Really large tubes had plates externally exposed capable of air or water cooling with elaborate seals to the glass parts. *Plate dissipation* is always a limiting factor in power applications.

The line marked *load line* shows the difference between the supply voltage V_{bb} and the voltage drop in a resistance R_L in series with the tube at any plate current, giving the plate voltage directly. The series resistance is mainly a plate resistor, but if there is a cathode resistor (for purposes of biasing) it should be included. There are generally different load lines for static (DC) and dynamic (AC) operation. As the grid voltage is

---

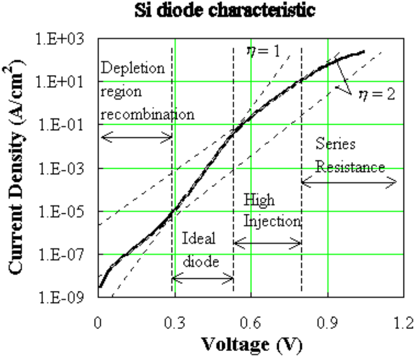

Figure 4.4.5: Current-Voltage characteristics of a silicon diode under forward bias.

characteristic, and a plot of I_b against V_g for a fixed value of V_p is called a *transfer characteristic*. From a family of either characteristics, the complete circuit behavior of the tube can be predicted. Unlike transistors, tubes of different types can have quite different (though similar) characteristics, so characteristic curves are much more important.

Let's begin with idealized plate characteristics for a triode, shown at the right. These are curved lines, but we represent them by straight lines for ease of understanding the various slopes and distances involved, which will be constant. Actual characteristics are not really far from straight lines, anyway. There is one curve for each grid voltage represented, which differ by a constant amount, here 2V. The horizontal distance between them, represented by the line labelled μ, is the amount the plate voltage must increase to hold the plate current constant; it represents the relative influence of plate and grid on plate current, and is the *amplification factor*. The vertical distance between them shows how much the plate current changes for a change in grid voltage. The ratio is a conductance, called the *transconductance*, denoted by g_m, measured in siemens (mho). The slope of the curves is the ratio g_m/μ, called the *plate conductance* g_p. With vacuum tubes, the reciprocal r_p was always used, called the *plate resistance*. Since actual

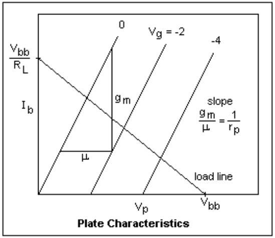

Plate Characteristics

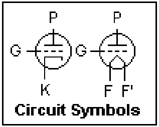
rectifier tubes, because they gave more current per watt of heating power. The indirectly heated, equipotential cathode that could be supplied by AC rather than by battery power was widely used after 1930.

A tube with just cathode and anode is called a *diode*, a term that has survived into the semiconductor age. Diodes were used for power or signal rectification, just like their semiconductor relatives. A "full-wave" diode has two anodes. When a control grid is provided, the tube is called a *triode*, and is used for amplification. Let's first study the peculiar circuit behavior of triodes, which will lead us to the reason for the addition of more grids, and the creation of the *pentode*, which turns out to act very much like a transistor.



Circuit symbols for a triode are shown at the right, and other tube symbols are derived from it. The connections are plate P, grid G, and cathode K or filament F, F'. These are analogous to the collector, base and emitter of a transistor, with the same polarities and direction of current flow as an NPN transistor. The circle is a part of the symbol. Grid connections can be to the right or left of the symbol, as convenient. A gas tube is indicated by a dot in the lower right-hand part of the circle. The heater of an indirectly heated cathode is usually not shown. A cold cathode (operating by positive-ion bombardment) is shown as a small circle. There are examples of these symbols below.

The important variables are the independent variables V_p and V_g, the plate and grid voltages (with respect to the cathode), and the dependent variable I_p, the plate current. A plot of I_p against V_p for a fixed value of V_g is called a *plate*

Germanium diode I-V Characteristics: Ideal behavior analysis

Abstract

This paper is devoted to the analysis of experimental results for a Germanium diode, and its comparison with the ideal diode theory. In particular, the I-V characteristics is measured for two different temperatures, showing a qualitative agreement with the predictions of the theory. Deviations from the ideal theory are presented and taken into account in a more detailed analysis of the forward bias characteristic. The temperature dependence of the reverse saturation current yields a value of the contact potential in good agreement with the known value of the gap for germanium.

1 Introduction

We analyze in this paper the experimental results for the I-V characteristics for a Germanium transistor ACY20, and compare them to the ideal diode theory. The ideal theory is based in simple assumptions of how the junction of two opposite doped semiconductors behaves when put together [1, 2, 3].

Measurements of the voltage and current across the diode at two different temperatures, t = 20dC and t = 80dC, are taken, showing a qualitative agreement with the predictions of the theory. Possible deviations from the ideal theory [1, 2, 3] are considered in a more detailed study of the forward bias characteristics, leading to several ranges of voltage where the ideal or ideal together with other mechanisms seem to dominate the current through the diode. The temperature dependence of the reverse saturation current allows us for obtaining an estimate of the contact potential, the potential barrier established between the two semiconductors of the junction. This value is in good agreement with the known value of the gap for germanium.

In section 2 we present the main features of semiconductors and junctions. Section 3 develops the simplest theory for the ideal diode, with a detailed calculation of the reverse saturation current from the underlying theory. Non-ideal mechanisms are outlined in section 4. The experimental set-up and measurement procedure are given in section 5, and section 6 contains the experimental results and their analysis. Finally our conclusion are presented in section 7.

2 The ideal diode

A diode is formed by the junction of two semiconductors doped with opposite sign, i.e., a p-n junction. The different electric character of the dopants at both sides of the junction establishes an electric field across the junction which determines the properties of the current which crosses the diode in the two different directions.

A n-type semiconductor is doped with elements called donors, because have electrons in excess of the intrinsic semiconductor elements (a semiconductor free of impurities or lattice defects is called intrinsic), e.g. phosphorous in silicon. The heavy doping density of donors, ND, determines the level of majority carriers, electrons in this case, so that nn0 = ND, while the

---

number indicates the heater voltage. 6 means 6.3V, 12 means 12.6V. Heaters are very forgiving of variations in voltage, but it is best to try to use the recommended voltages. AC is generally used, supplied from a small transformer. It is necessary to make sure that the difference in voltage between heater and cathode does not exceed 90V, so the heater AC supply should be grounded. It is usual to ground the center tap on the transformer for this purpose. Tubes for battery radios have plain filaments that are both heater and emitter, and must be supplied with DC. Their type numbers begin with "1" and are intended to be used with a standard dry cell of 1.5V. Larger tubes for high voltages have to use thoriated-tungsten filaments at 2000K,a bright yellow, to avoid damage from positive-ion bombardment, small as it may be. Heaters are sometimes called filaments, and the heater supply the filament supply, out of linguistic inertia.

Before the 1930's, each manufacturer used arbitrary designations for his tubes, and there was no uniformity or system. Tubes were first systematically identified in the U.S. by three-digit numbers, where the first digit denoted the manufacturer. For example, a type x10 was a power triode, a type x36 a screen-grid tetrode, where x was the manufacturer's number (usually omitted). Later, a new system was introduced where the first digit gave the filament or heater voltage, and the last digit gave the number of functional electrodes. This scheme was introduced by the RMA (Radio Manufacturer's Association) in 1934. A letter between these digits was assigned in order of introduction. For example, a 2A3 was a power triode with a 2.5 V filament (this popular tube is, remarkably, still in use for hi-fi amplifiers because of its low distortion!). This system was not comprehensive enough, and in the final system, the first number designated the heater voltage, but the remainder of the designation was arbitrary. Filaments were customarily used, especially in power and so electrons can pass through without hindrance. When it is made negative, it opposes the effect of the anode in creating an electric field, but does not attract any electrons, and so draws no current (except for the positive-ion current mentioned above). If it is made sufficiently negative, it can *cut off* the plate current entirely. If it is made positive, it can enhance the plate current, but then draws some *grid current* itself. The grid provides a sensitive control, using negligible power, of the large plate current, so the vacuum tube is a powerful amplifying device.

Early radio sets were battery-powered (domestic electrification was in its infancy, and absent in rural areas, when radio began), and a convention was established for identifying the batteries required. The filaments required low voltages at high currents (2W or more each), and their supply was called the A battery. The plates required high voltages at small currents, perhaps 90V at a few mA, and their supply was called the B battery. Grid bias was required, to hold the grids negative, demanding low voltages at small currents, and the corresponding battery was the C battery. The notations A and C were later little-used (except for actual battery radios), but the plate supppy came to be generally known as B+, and the letter B appears in subscripts of quantities referring to the plate circuit.

The cathodes of receiving tubes consist of a sleeve of nickel alloy coated with a compound of alkaline-earth oxides (Ba and Sr, usually). Inside is a tungsten heater wire insulated from the cathode with BeO or alundum (aluminum oxide) ceramic insulation. These cathodes must be heated only to about 850K (a dull red) to emit electrons in the amount necessary. Most receiving tubes require 6.3V or 12.6V for their heaters, at about 0.30A or 0.15A, respectively. Every tube type is identified by a type number, such as 6J5, where the first

---

density of minority carriers is determined from the mass action formula

$$np = n_i^2 = N_V N_C e^{-E_g/kT}$$

(2.1)

which leads to

$$n_{n0} = N_D, \qquad p_{n0} = \frac{n_i^2}{N_D} = \frac{N_V N_C}{N_D}\, e^{-E_g/kT}$$

(2.2)

where NV and NC are the density of states at the top of the valence and at the bottom of the conduction band respectively, and Eg is the band gap of the semiconductor.

Equally a p-type semiconductor is doped with acceptors, which have less electrons than the main element of the material (boron in silicon), and then trap one electron leaving a vacancy in the valance band, which is represented as a hole. Again, the doping density of acceptors, NA, determines the hole concentration in a heavily doped material, and the electron concentration is obtained from the mass action formula:

$$p_{p0} = N_A, \qquad n_{p0} = \frac{n_i^2}{N_A} = \frac{N_V N_C}{N_A}\, e^{-E_g/kT}$$

(2.3)

Now that we know the main features of n-type and p-type semiconductors isolated we put them next to each other. We assume here that we can treat electrons and holes independently. In this case the excess of electrons in the n-type side will diffuse into the p-type side. This diffusion effect produces a depletion of carriers around the interphase, known as the depletion region, the depletion will be supposed to be complete. Therefore producing an uncompensated charge to both sides of the junction which gives rise to an electric field (assumed to be contained exclusively within the depletion region). This electric field, in turn, generates a drift current opposite to the diffusion current, until an equilibrium between the two processes is reached.

$$I_{\text{diff}} = qD_p\frac{dp}{dx},$$
$$I_{\text{drift}} = qp\mu_p E, \qquad E = -\frac{dV}{dx} \quad (2.4)$$

Taking into account the Einstein relation Dp = kT¹p=q it is straightforward to obtain a relationship between the carrier density to both sides of the junction,

$$\frac{p_{p0}}{p_{n0}} = \frac{n_{n0}}{n_{p0}} = e^{qV_0/kT} \quad (2.5)$$

where V0 = Vn ¡ Vp is the potential drop across the junction generating the drift electric field, also known as built-in or contact potential. By using eqs. (2.2), (2.3) and (2.1) into (2.4) we can write

$$qV_0 = kT\log\frac{N_A N_D}{n_i^2} = E_g + kT\log\frac{N_A N_D}{N_V N_C} \quad (2.6)$$

which relates linearly the contact potential and the gap up to an additive factor depending on temperature, doping and density of states.

3 I-V Characteristic for an ideal diode

We can determine the general shape of the current flow through the junction considering a general argument for the mechanisms implied in the formation of the diode (see for example ref. [1], page 169).

The electrons emitted by the thermionic cathode form a negative *space charge* cloud around the cathode, dense enough that if no electrons are removed by attraction to the anode, the rate of emission is equal to the rate of return. When the anode is made positive, some of the electrons are attracted to it out of the space-charge cloud, and a *thermionic current* results. The amount of this current is given by $I = A\ V^{3/2}$, where V is the voltage from anode to cathode. This is called the Langmuir-Child law, and shows that electric field at the space charge produced by the anode controls the electron current. The cathode emits electrons copiously, so much that there are always enough electrons available to satisfy Langmuir-Child. Of course, at a sufficiently high anode voltage, the current may *saturate*, when all the emitted electrons are attracted to the anode, but this never occurs in normal operation, so small variations in cathode temperature have no effect. The current in a vacuum tube is said to be *space-charge controlled*.

If enough gas is present in the tube, the positive ions can counterbalance the negative electron space charge, robbing the anode of control and greatly increasing the current. Also, the positive ions can take over a large part of the electron emission at the cathode. Such tubes make efficient rectifiers, and the gas pressure can be quite low, as in some rectifiers, or rather high, as in a mercury-arc rectifier. In receiving tubes, positive ion collisions can destroy the delicate, high-efficiency cathode surface. Positive ions also cause small currents to negative electrodes that otherwise might be expected to carry no current at all. For all these reasons, receiving tubes have a high vacuum.

The electric field at the space charge that controls the current does not have to be created by the anode alone. A third electrode, the *grid*, is placed between the cathode and the anode, closer to the cathode. It is made of a spiral of fine wire, filaments used low voltages and high currents, and had a short life because of the high temperatures required for adequate emission. Most radio sets had a rheostat to adjust the filament current properly. Wehnelt emitters would have been quickly destroyed by positive-ion bombardment in these tubes. Apparently by accident, thoriated tungsten wire was used in a trial at the GE factory in Harrison, NJ in 1920 on a UV201 tube. Thoriated tungsten gave 75 mA/W of filament power, while tungsten gave only 1.75. Thoriated-tungsten filaments became popular for receiving tubes, such as the UV201A, which was an improved UV201, around 1924. Its filament required 0.25 A at 5 V, while the UV201's had required 1.0 A. Since tubes were now all *hard*, or high-vacuum tubes, indirectly heated oxide-coated cathodes, which gave copious emission at low temperatures, were used almost exclusively in receiving tubes after 1930. Not only did these cathodes have a long life, but were also *equipotential*, making circuit design simpler. Thoriated tungsten remained for transmitting tubes, where a rugged emitter was necessary because of the higher plate voltages, but even here tungsten was the only suitable choice for really high voltages, to avoid damage from positive-ion bombardment.

The rate of emission of electrons from a heated metal is given by the Richardson-Dushman equation, $i = AT^2e^{-b/T}$ A/cm^2, where T is the absolute temperature in K, and A and b are constants typical of the emitter. For tungsten, A = 60 and b = 52,400K, while average values for an oxide cathode are A=0.01, b = 11,600. The exponential factor has by far the largest influence, so emission increases rapidly with temperature. This makes thermionic cathodes very suitable even for heavy currents. In all tubes, electrons are emitted in far greater numbers than required; most simply return to the cathode.

As it was shown before there are two mechanisms which give rise to the diode conducting properties. On one hand there is the diffusion of electrons from the n-type side into the p-type side. These electrons have to overcome the potential barrier (contact potential) established by the electric field of the junction. This is achieved by a pure thermal activation mechanism

$$n \sim e^{qV_0/kT} \qquad (3.1)$$

and therefore the density of carriers overcoming the potential barrier depend on the height of the barrier (given by the contact potential V0), and the temperature.

This diffusion current is compensated by a drift current originated by the electric feld across the junction. Differently to the diffusion mechanism this drift current is not very much affected by the variations in the contact potential between the two sides of the junction, since the electric feld acts on the minority carriers, and is the small density of them which determines the flow rather than the electric field itself.

We can assume therefore that in equilibrium V = 0 the diffusion and drift currents are compensated, and are both given by I0. When we apply a forward bias on the diode V > 0 the potential barrier is reduced from V0 to V0 ¡ V , and therefore the diffusion current increases by a factor eqV=kT , while the drift current remains unchanged. In the case of applying a reverse bias V < 0 the diffusion current will be reduced by a factor e¡qjV j=kT , while again the drift current is unaffected.

From the previous argument we can establish the I-V characteristic for the diode

$$I = I_0 \left(e^{qV/kT} - 1\right) \quad (3.2)$$

where I0 represents the equilibrium diffusion and drift current for V = 0. Notice that for and infinity reverse bias the diffusion current goes to zero and the only remaining one is the drift, such that I(V = ¡1) = ¡I0, a small finite value known as reverse saturation current. On the other hand, for large forward bias the current across the junction increases exponentially, and it is completely dominated by diffusion.

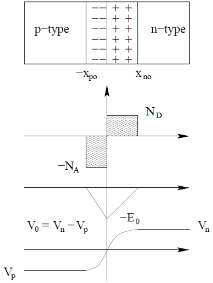

Figure 1. Ideal abrupt p-n junction, charge distribution, profile of the electric field and contact potential across the junction.

3.1 Reverse saturation current I0

Now that we have obtained the general expression for the I-V characteristics of the current across a p-n junction we will turn to compute the value of the reverse saturation current I0 under

"receiving" comes from their use in radio receivers, their principal commercial application, but refers to all small vacuum tubes for general electronic purposes. For the cathode-ray tube and making your own oscilloscope, see The Cathode-Ray Tube.

The electrons move from the cathode (K), the negative electrode, to the anode or *plate* (P), the positive electrode. Conventional current is in the opposite direction. The electrons are liberated at the cathode by heat--thermionic emission--or as a result of bombardment by positive ions, which can cause emission of electrons or even heat the cathode the required amount for thermionic emission. All receiving tubes employ thermionic emission, though we will note certain examples of *cold cathodes* in special cases. These were not usually really cold, but heated by ion bombardment rather than by a current supplied externally. The space in which the electrons move is not completely devoid of gas, so some gas molecules may be *ionized* by collision with speedy electrons, when an electron is knocked off, leaving a *positive ion*. The positive ions move in the opposite direction to the electrons (but their current is in the same direction, since they are of opposite charge). The effect of positive ions in a receiving tube is very small, because of the very high vacuum that is used.

Self-heated electron emitters are called *filaments*. The carbon filaments of the Edison Effect were soon replaced by metallic emitters, usually tantalum or tungsten, which were used by Fleming and de Forest. In Germany, Arthur Wehnelt discovered in 1903 that barium or calcium oxides baked on a platinum base emitted copiously, and used these *oxide-coated* emitters on vacuum rectifiers evolved from discharge tubes, which he patented in 1904. However, the use of *soft* tubes, which contained residual gas, demanded the use of rugged tungsten filaments, which dominated in 1910-20. These

1904 (B.P. 24850), where a filament and plate were arranged in the same envelope in a rather low vacuum, which could be used as a rectifier, or as a rather insensitive radio detector. In 1907, Lee de Forest patented the *triode* (which he called the Audion; the term "triode" was not used until much later, after it threated to become a trade name), in which a third electrode, the grid, was introduced to control the electron stream. This made a more sensitive detector, but the amplifying property was not used at first, and de Forest, who did not understand well what was going on, defended gassy tubes with their gas amplification. The introduction of high vacuum, as well as improved materials and processes, especially metal-to-glass seals, created a very useful amplifying device that allowed great developments in radio, telephony and sound reproduction. Schottky suggested a screen grid between the plate and control grid to make the electron tube useful at higher frequencies in 1919 (and actually made tubes with a second grid, but this was for space-charge control), but this was only realized by Hull and Williams in 1928 in radio receivers. The metal tube was introduced in 1935, but glass envelopes never disappeared and were constantly improved. The final pattern of electron tube was the "miniature" or all-glass type, which became the predominant receiving-type tube after about 1945. Transistors were invented in 1948, and in the next decade were improved to the point where they could take over most of the amplifying applications of electron tubes at much lower cost, and with greater reliability. Electron tubes remain in use as cathode-ray tubes, magnetrons, X-ray tubes, and for handling large powers. They were remarkable devices, using many sophisticated materials and processes, yet were widely available at low cost. We shall look here mainly at examples of *receiving tubes*, the smaller amplifying devices that have been completely replaced by semiconductors in current practice, but nevertheless will deepen our knowledge of electronics, while being fascinating to study. The name

the assumption that it is generated by low level (minority carrier) injection. In this approximation the majority carrier density is unaffected.

As shown in fig. 1 we suppose as a good approximation that we can treat electrons and holes independently, and that the drop of the contact potential is produced within the depletion region.

Assuming that the depletion region is completely depleted of carriers we have two regions with opposite charge, and densities equal to the doping, NA for the p-type side, and ND for the n-type one. This uniform charge produces a linearly spatially distributed electric field and a quadratically distributed contact potential, as show in fig. 1.

Under the previous conditions the current across the junction is established by the minority carrier injection on the other side of the junction. For example, holes will be injected

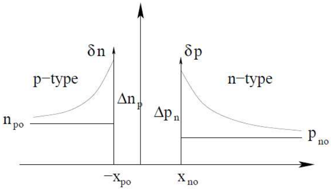

Figure 2. Profile of the low level injection in the p-n abrupt junction.

from the p-type side into the n-type side, and its concentration will decay to the equilibrium n-type hole concentration, pn0, due to recombination of the injected holes, as shown in fig. 2. Then, the concentration of holes in the n-type semiconductor is given by

$$\delta p = \Delta p_n \, e^{-(x-x_{n0})/L_p} \qquad (3.3)$$

and a similar expression for electrons,

$$\delta n = \Delta n_p \, e^{(x+x_{p0})/L_n} \qquad (3.4)$$

where xn0, xp0, Lp, Ln are the border of the depletion region in the n-type and p-type sides and the hole and electron diffusion lengths. ¢pn ´ p(xn0) ¡ pn0 is the excess of holes over the bulk n-type hole concentration at the n-type border of the depletion region. Similarly for ¢np ´ n(¡xp0) ¡ np0 for the p-type side.

The current passing through xn0 is given by the diffusion

$$I_p(x_{n0}) = -qAD_p \left.\frac{d(\delta p)}{dx}\right|_{x_{n0}} \qquad (3.5)$$

A similar expression to that in eq. (2.5) for the relation of carriers to both sides of the junciton under equilibrium conditions can be derived for the case of a forward bias, i.e. V > 0. The effect of a forward bias is to reduce the potential barrier to V0 ¡ V , and therefore the relationship between the holes in both sides of the junction is now given by

$$\frac{p(-x_{p0})}{p(x_{n0})} = e^{q(V_0-V)/kT} \qquad \longrightarrow$$

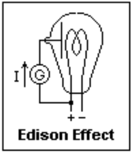
$$\Delta p_n \equiv p(x_{n0}) - p_{n0} = p_{n0}(e^{qV/kT} - 1) \qquad (3.6)$$

Theory of Vacuum Tubes

J. B. Calvert
Created 17 August 2001
Last revised 8 April 2003

http://mysite.du.edu/~etuttle/electron/elect27.htm#Diodes

Miniature vacuum tubes with cathodes of high-field-emitting carbon nanotubes are currently under study at Agere Systems in Murray Hill, NJ. A triode with amplification factor of 4 has been constructed, with an anode-cathode spacing of 220 μm, and a pentode is planned. Vacuum tubes may return to electronic technology! See *Physics Today*, July 2002, pp. 16-18.



Devices in which a stream of electrons is controlled by electric and magnetic fields have many applications in electronics. Because a vacuum must be provided in the form of an evacuated enclosure in which the electrons can move without collisions with gas molecules, these devices were called *vacuum tubes* or *electron tubes* in the US, and *thermionic valves* in Britain. In 1883, Thomas Edison observed that a current flowed between the filament of an incandescent lamp and a plate in the vacuum near it (see figure at the right), when the plate was connected to the positive end of the filament, but not when the plate was connected to the negative side (the plate was actually between the two legs of the filament). No important application was made of this unexplained *Edison Effect* at the time. In 1899, J. J. Thomson showed that the current was due to a stream of negatively-charged particles, electrons, that could be guided by electric and magnetic fields. Fleming patented the *diode* in

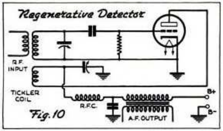


Fig. 10

ranged that part of the amplified signal is fed back to the grid to be reamplified. The feedback is supposed to be just a little too weak to sustain self-excited oscillation, the trick being to adjust the feedback just right.

A modification of this, the super-regenerative circuit, has several interesting and useful features. Though tricky, it's exceedingly sensitive and sharp-tuning. Essentially it is a regenerative detector, but a "quench circuit" consisting of a triode and an inductance-resistance network acts to interrupt its functioning at a supersonic frequency. The theory of its operation is ingenious. An ordinary regenerative detector with a little too much feedback will hesitate for a fraction of a second, then gradually sweep into oscillation. The super-regenerative detector has so much feedback as to cause oscillation, but the quench circuit keeps interrupting it before the oscillation can establish itself. This permits a tremendous amount of reamplification. The circuit is particularly useful on frequencies of 100 megacycles and above, where tube losses tend to be severe, for the principle permits B power to replace such losses.

The problem of demodulating F.M. signals is quite different from that with A.M.

In Fig. 11 the R.F. input is fed to a special intermediate-frequency transformer that has two secondary circuits, S_1 and S_2, each of which drives a conventional diode detector and filter circuit. (Usually one 6H6 dual-diode detector tube is used.) If the intermediate frequency of this receiver is 5.00 megacycles, the primary of the "discriminator transformer" would be tuned to the same value, S_1 tuned to 5.10, and S_2 to 4.90 megacycles. If the signal comes through at 5.00 megacycles, both secondaries and their associated detectors receive an equal voltage; and since the filter circuits are so arranged as to oppose the voltages, they cancel each other and no A.F. is produced. But when the signal frequency varies either up or down, it will approach the resonance of one secondary and move farther away from that of the other. One will get a decreased and the other an increased voltage, and a net voltage will appear across the audio output. Since the voltage across the audio-output terminals will increase as the R.F. signal departs from 5.00 megacycles, audio volume will be determined by the extent of frequency deviation. Audio pitch will likewise be determined by the number of times a second that frequency deviation occurs. The circuit therefore meets the required conditions of F.M. demodulation.

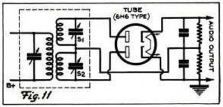

Fig. 11

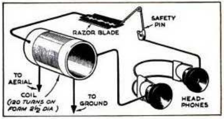
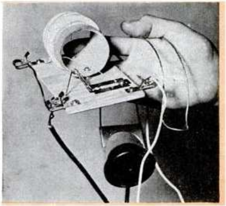
Lt. M. L. Rupert's "foxhole radio," used on the Italian front, gets reception on a razor blade. O. B. Hanson, chief engineer of N.B.C., improved it by tying pencil lead to the pin point. Wire gauge is not critical, but good headphones, a long aerial, and patience in locating a sensitive spot on the razor blade are all requisite





Plugging (3.6) into (3.5) and differentiating we obtain an expression for the current at the border of the depletion region xn0

$$I_p(x_{n0}) = qA\frac{D_p p_{n0}}{L_p}\left(e^{qV/kT} - 1\right) \tag{3.7}$$

and therefore the total current, adding up the electronic part, is given by

$$I = qA\left[\frac{D_p p_{n0}}{L_p} + \frac{D_n n_{p0}}{L_n}\right]\left(e^{qV/kT} - 1\right) \tag{3.8}$$

from where we can easily read I0.

After using eqs. (2.2), (2.3) and (2.5) we can rewrite the reverse saturation current as

$$\begin{aligned} I_0 &= qA\left[\frac{D_p}{N_D L_p} + \frac{D_n}{N_A L_n}\right] N_V N_C\, e^{-E_g/kT} \\ &= qA\left[\frac{D_p N_A}{L_p} + \frac{D_n N_D}{L_n}\right] e^{-qV_0/kT} \end{aligned} \tag{3.9}$$

which provide an explicit expotential dependence on the temperature and energy gap, or contact potential, assuming the terms inside the square brackets cancel each other or have a subdominant temperature dependence.

4 Non-ideal mechanisms

There are several aspects which have not been taken into account in the above derivation of the I-V characteristics, and further complicate the understanding of the diode behavior (ref. [1], page 211):

Recombination within the depletion region: We assumed that there was no generation-recombination processes in the depletion region. For material with a small density of carriers the depletion region can be quite large and then the probability of recombination inside the depletion region is higher even dominating the shape of the curve. The recombination rate is proportional to

$$R \sim 1/n_i \sim e^{qV/2kT} \quad (4.1)$$

Generation within the depletion region: For reverse bias what it is important is the rate of generation, since as soon as pairs are generated they are swept away by the enhanced electric field

$$G \sim W \sim \sqrt{V} \quad (4.2)$$

High level injection: As commented before we supposed that the density of majority carriers was not affected. However, as we increase the potential drop a large amount of carriers is taken from one side of the junction to the other, and injection for the majority carriers must be considered. When this is done we can see that the forward bias is dominated by the following form of the current:

$$I \sim e^{qV/2kT} \quad (4.3)$$

Ohmic losses: The potential drop inside the p and n regions, as well as that in the contacts, can be taken into account by introducing a series resistance Rs in the diode, which will influence the measurements as we use an external tension $V = V_{\text{ext}} - IR_s$.

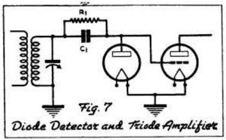


Fig. 7

Diode Detector and Triode Amplifier

The diode detector is commonly used today. It can handle very strong signals without overloading, has excellent fidelity, and is simple and reliable. However, it isn't extremely sensitive, since the filter system imposes a load that draws power from the tuned circuit. This in turn reduces selectivity.

Fig. 7 shows a modified diode detector directly coupled with a triode amplifier. Here the filter circuit operates somewhat differently; when a positive R.F. signal comes along, the 250-mmf. condenser C_1 transmits it freely, applying a positive potential to the diode plate and drawing electrons from the filament until the charge on the condenser is neutralized. This may take less than a ten-thousandth of a microsecond. When the positive peak declines to zero, the electrons are trapped on one plate of the condenser, on the plate of the diode, and on the triode grid. Their only escape is through the high-resistance shunt, and it takes more nearly ten thousand microseconds than a ten thousandth of a microsecond for the charge to leak away. Thus the charge on the condenser can increase at radio frequencies but can decrease only at audio frequencies. Since it is applied directly to the triode grid, the triode plate current will follow A.F. modulation.

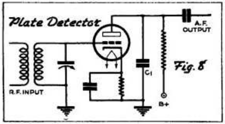

Plate Detector

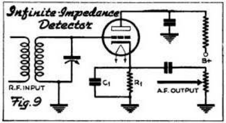
Fig. 8

The grid of a triode is quite capable of collecting electrons from the filament, and consequently can serve as a diode plate in itself. In the grid-leak detector of years past, a single triode was used to perform this double function. The grid-leak detector was selective, though the fidelity was not high and it tended to overload on strong signals. It is seldom used today.

The circuit of a plate detector is shown in Fig. 8. The high value of the cathode resistance makes the grounded grid strongly negative with respect to the cathode, so much so as to cut off the plate current when there is no signal. When a negative signal reaches the grid, practically no change of plate current occurs, for it's already nearly zero. Bút when a positive signal arrives, the strong bias is decreased and plate current flows. This gives the nonlinear reaction necessary for demodulation. Condenser C_1 shunts the R.F. pulses to the ground. Able to handle fairly heavy signals, the plate detector shown gives good fidelity. It imposes no load on the tuned circuit and hence has good selectivity.

The infinite-impedance detector, so called because it has almost infinite resistance to R.F. between grid and ground, and hence places no load on the tuned circuit, is illustrated in Fig. 9. A positive signal applied to the grid permits the plate current to flow, and this causes a voltage drop through R_1 that drives the cathode positive. Since there is always some current flowing through the tube, the cathode is always somewhat positive with respect to the grid, and no grid current flows. Whatever the positive potential of the grid, the cathode will rise to match it, though it won't follow the negative swings as rapidly because of C_1. The result is that the potential across R_1 exactly follows the peaks of the R.F. signal. There is no amplification, but the detector has excellent fidelity, will handle strong signals, and is much used today.

Fig. 10 is the regenerative detector, of evil memory. It has excellent sensitivity and selectivity, but against these are poor fidelity, extreme unreliability, complexity of operation, and a bad tendency to turn into a transmitter able to send out squeals and howls into neighboring counties. Outlawed on broadcast frequencies now, it is still used by some amateurs on short-wave receivers. Basically it is a grid-leak detector so ar-



Infinite-Impedance Detector

Fig. 9

AND HOW THEY WORK

derstood phenomenon in which certain metallic oxides exhibit the ability of rectifying A.C. The plate-and-needle detector, essentially a metal needle resting lightly on a metal plate, embodies this principle, as does the razor-blade radio shown on page 209.

One of the most sensitive instruments known in the early days of wireless was the galvanometer. Unfortunately, it requires direct current; if it is fed A.C. of even moderate frequencies, the needle tries to swing one way on positive impulses and the other way on negative ones, with the result that it stands quite still. Before it could detect R.F., it had to be coupled with a rectifier that would intercept half the R.F. wave.

To improve the detector, the British Marconi Company called in Dr. J. A. Fleming, a leading English research physicist. Fleming had already done some notable research for a lamp-bulb manufacturer. The carbon-filament lamps of the time had a tendency to burn out at the positive end of the filament, due to the "Edison Effect." Edison had reported that a hot filament in an evacuated tube would retain positive but not negative charges—in modern terms, that it would give off electrons. Therefore electrons jumped from the negative end to the positive, carrying part of the current and heating the positive end by bombardment.

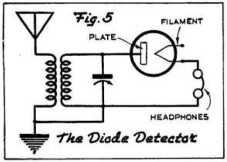
B
RECTIFIED R.F. AFTER PASSING DETECTOR
NEGATIVE IMPULSES CUT OFF BY CRYSTAL
Fig. 4
C
PHONES RESPOND TO A.F. RESULTING FROM CHANGES IN AMPLITUDE OF RECTIFIED R.F.

Dr. Fleming's studies of the Edison effect, plus his realization that the galvanometer would make a sensitive detector if it could be used with R.F. currents, gave him the answer—the Fleming Valve. It was a simple diode rectifier, a heated filament and a plate in an evacuated envelope, in series with a galvanometer and the antenna circuit. The diode permitted one half of the waves to kick the moving coil, but blocked the opposite set of half-waves. Before long headphones, taken over from the telephone, were used in place of the galvanometer and found unexpectedly efficient (Fig. 5).



Essentially, a demodulating detector is a nonlinear element—one that will pass more current in one direction than in the other—followed by a filter circuit. (A diode can be made to pass 95 percent of one half-wave and none of the other; a crystal may pass 80 percent of one and 40 percent of the other. So long as conductivity is dissimilar, demodulation will take place.)

In the simple diode detector shown in Fig. 5, the headphones themselves constitute the filter; the phone coils have sufficient inductance and capacitance to make an excellent R.F. trap. In Fig. 6, which shows a more modern version of the diode detector, a resistance-capacitance filter is used instead. The condensers and resistors are of such values that the condensers discharge through the resistors only at comparatively low frequencies—15,000 cycles a second or less—with the result that the ultrarapid R.F. pulses are completely smoothed out and only modulation remains. *[Turn the page]*

5 Experimental Procedure

In order to compare the theory of the ideal diode with the real diode behavior we will measure the current crossing a Germanium transistor ACY20 when a tension is applied across it, in forward and reverse bias.

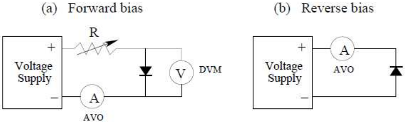

Figure 3. Experimental set-up for the forward and reverse bias configuration of the electric circuits to measure the I-V characteristic of the diode.

As shown in fig. 3a for forward bias an external voltage is applied to the diode and a series varistor, and the voltage drop on the diode, as well as the current, are measured. In fig. 3b the set-up for measuring reverse bias is shown. In this case the varistor is not necessary any more, since the variations in current as voltage is changed are small, and therefore the tension drop can be directly read from the voltage source.

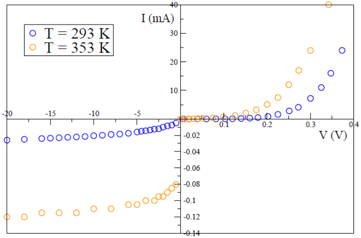
At room temperature we measure the I-V characteristics by controlling the current for forward bias ($I < 40mA$), and taking care of obtaining enough data for small values of the voltage ($0V < V < 0{:}2V$) in order to capture the expected exponential behavior of the characteristic. For reverse bias we can control the voltage itself and stop the reading before reaching the breakdown point.

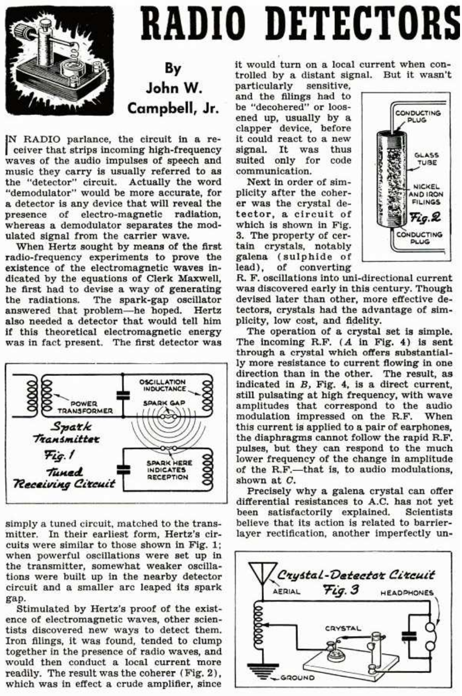
In order to verify the exponential behavior of the reverse saturation current I0 with temperature (and energy gap Eg or contact potential V0), we heat the sample, while in the reverse bias set-up, for a given value of the applied voltage, V = ¡5V , from room temperature up to a temperature of about t = 80oC.

A new measurement of the I-V characteristic at about t = 80C is performed following the same procedure used for the room temperature case. We should obtain an increment of the current, in both forward and reverse bias, due to the thermal activation of the density of carriers, as predicted by the theory.

6 Experimental Results

We present in this section our results obtained from the previously described experimental set-up for a germanium diode. First of all, in fig. 4 we can see the I-V characteristic for forward and reverse bias, at room temperature (t = 20dC) and t = 80dC. (Notice the different scale used for the positive and negative axes of voltage and current).





RADIO DETECTORS

By
John W.
Campbell, Jr.

IN RADIO parlance, the circuit in a receiver that strips incoming high-frequency waves of the audio impulses of speech and music they carry is usually referred to as the "detector" circuit. Actually the word "demodulator" would be more accurate, for a detector is any device that will reveal the presence of electro-magnetic radiation, whereas a demodulator separates the modulated signal from the carrier wave.

When Hertz sought by means of the first radio-frequency experiments to prove the existence of the electromagnetic waves indicated by the equations of Clerk Maxwell, he first had to devise a way of generating the radiations. The spark-gap oscillator answered that problem—he hoped. Hertz also needed a detector that would tell him if this theoretical electromagnetic energy was in fact present. The first detector was simply a tuned circuit, matched to the transmitter. In their earliest form, Hertz's circuits were similar to those shown in Fig. 1; when powerful oscillations were set up in the transmitter, somewhat weaker oscillations were built up in the nearby detector circuit and a smaller arc leaped its spark gap.

Stimulated by Hertz's proof of the existence of electromagnetic waves, other scientists discovered new ways to detect them. Iron filings, it was found, tended to clump together in the presence of radio waves, and would then conduct a local current more readily. The result was the coherer (Fig. 2), which was in effect a crude amplifier, since it would turn on a local current when controlled by a distant signal. But it wasn't particularly sensitive, and the filings had to be "decohered" or loosened up, usually by a clapper device, before it could react to a new signal. It was thus suited only for code communication.

Next in order of simplicity after the coherer was the crystal detector, a circuit of which is shown in Fig. 3. The property of certain crystals, notably galena (sulphide of lead), of converting R. F. oscillations into uni-directional current was discovered early in this century. Though devised later than other, more effective detectors, crystals had the advantage of simplicity, low cost, and fidelity.

The operation of a crystal set is simple. The incoming R.F. (*A* in Fig. 4) is sent through a crystal which offers substantially more resistance to current flowing in one direction than in the other. The result, as indicated in *B*, Fig. 4, is a direct current, still pulsating at high frequency, with wave amplitudes that correspond to the audio modulation impressed on the R.F. When this current is applied to a pair of earphones, the diaphragms cannot follow the rapid R.F. pulses, but they can respond to the much lower frequency of the change in amplitude of the R.F.—that is, to audio modulations, shown at *C*.

Precisely why a galena crystal can offer differential resistances to A.C. has not yet been satisfactorily explained. Scientists believe that its action is related to barrier-layer rectification, another imperfectly un-

Figure 4. I-V Characteristics: values for t = 20dC and t = 80dC. Notice that the scale for positive and negative axis is different.

For forward bias we notice an exponential behavior (a more detailed study is presented in fig. 5) of the characteristics, and how the higher temperature characteristic allows for higher values of current in agreement with the assumption of a larger number of carriers available due to thermal activation.

In the reverse bias scenario we can see how the current tends to saturation. A saturation point is not reached probably because of generation current within the depletion region, or other kind of non-ideal mechanism as we will discuss later. Again the higher temperature curve yields a higher current.

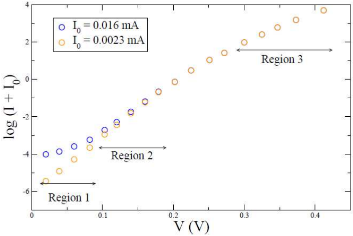


Figure 5. Ideality Factor: measurements in forward bias. Three different regions are identified, corresponding to different dominant mechanisms. Low voltage (region 1), low-intermediate voltage (region 2), and large voltage (region 3) regions are indicated in the figure.

The confirmation of the exponential behavior for the forward bias characteristic is presented in fig. 5. According to eq. (3.2), by plotting log(I + I0) against V we should obtain a straight line if the diode followed the ideal behavior. When non-ideal mechanisms are considered, as those presented in section 4, different regimes should be identified as the slope of the curve changes, since

$$\frac{qV}{kT} \longrightarrow \frac{qV}{AkT} \quad (6.1)$$

where A is known as the ideality factor. Usually A = 1 for the ideal mechanism, corresponding to low injection current, and A = 2 for high injection current (large voltage) or recombination current within the depletion region. In general intermediate values are expected since all the effects work at once.

There is a further uncertainty, since we do not know with precision the value of the reverse saturation current I0. Although in principle we are asked to take the value for a voltage of V = ¡5V , I0 = 0:016mA, we will argue that it is as reasonable to choose as saturation current the value for V = ¡0:05V , I0 = 0:0023mA. Other intermediate values of the saturation current would lead to intermediate results for ideality factors in the low voltage region. Curves for both saturation currents chosen are shown in fig. 5.

We can divide the points in fig. 5 in three regions, low voltage (0V < V < 0:1V , (region 1), low-intermediate voltage (0:1V < V < 0:2V , region 2), and large voltage (V > 0:3V , region 3) regions. By determining the slope of the linear fitting in each region we can obtain different ideality factors for each region and curve (m = q=AkT, see eq. (6.1)). The results for A are presented in table 1.

low band. About 1-2 wire diameter spacing between the two windings is recommended.

experienced when using a conventional inductor. If greater selectivity is needed at the high end of the BC band when using a conventional inductor, antenna coupling must be reduced and/or the diode must be tapped down on the tank to raise the loaded Q. Either approach results in a greater insertion power loss and a weaker or inaudible signal to the phones when tuning stations near the high end of the BC band . The low inductance (parallel connection) of the contra-wound inductor enables a 4 times reduction in bandwidth at 1710 kHz, compared to results with conventional inductor. This reduces the need to tap the diode down on the tank and re-match the antenna when one needs to increase selectivity, as mentioned above.

Note:
One could use two separate conventional non-coupled inductors, one of 250 uH and the other of 62.5 uH, instead of a contra-wound configuration. This is not recommended because the Q of the 62.5 uH inductor will probably be less than that of the 250 uH unit unless it is made physically as large as the contra-wound coil.and employs larger diameter wire. Also, when using the contra-wound approach the hot end of the inductor, when the two coils are connected in parallel, can be in the center of the overall unit, with the outer wire ends of the assembly placed at ground potential. This reduces electric field coupled losses from end mounting brackets and surroundings.

The inductances of the two connection configurations (parallel and series) of a contra-wound coil will depend upon how closely spaced the two windings are placed, but, the ratio of the inductance of the series to that of the parallel connection always remains at 4 times no matter how far or close together the windings are placed. Remember that overall distributed capacity is greater when using the parallel connection in the

---

Region	Io (mA)	A
1	0.016	3.10
2	0.016	1.45
3	0.016	2.58
1+2	0.0023	1.31

Table 1. Ideality factor for the different regions and curves in fig. 5

Our first curve (Io = 0:016mA) presents, in the low voltage region, a much larger value of A than expected from a recombination in the depletion region mechanism. In the low-intermediate region we could suggest a mix presence of recombination and ideal mechanisms. For the high voltage region a high value of A = 2:58 is obtained, which suggests that not only high level mechanisms are present. For slightly smaller values of the voltage drop (0:25V < V < 0:35V) a better agreement with high level injection current can be achived. The large value of A suggests that ohmic losses must be considered, which reduces the net current through the device.

We have considered as well the value I0 = 0:0023mA because at room temperature, kT » 25meV , the saturation of the current in reverse bias should be obtained for values of the reverse voltage as small as V » ¡0:05V . The existence of other effects in reverse bias (ref. [1], fig. 5-37, page 218), as pair generation in the depletion region, enhances the current, which will be misleading when trying to fit the ideal behavior. The smaller value of the saturation current in this case smoothers the curve for low voltages, and we can obtain a nice linear behavior spanning regions 1 and 2, with a value of the ideality factor A = 1:31, which is closer to ideallity. This value can be obtained when considering recombination in the depletion region due to interphase recombination, or defects in excess to what would be ideal.

Eq. (3.9) provides an explicit temperature dependence of the reverse saturation current with temperature, namely, an exponential behavior (provided we assume that the temperature dependence of the terms in square brackets cancels each other, or at least is subdominant). We can use the data of the saturation current, measured at V = ¡5V in the range of temperatures of t = 20d ¡ 80dC to obtain a value for the contact potential.

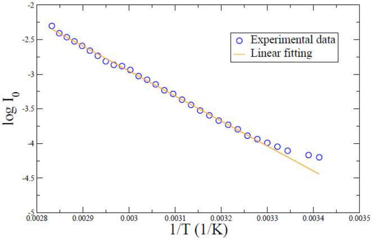

Figure 6. The contact potential is obtained from the slope of the linear fitting. This value is to be compared with the energy gap for Germanium. In the linear fitting the five most right experimental points where dropped.

In fig. 6 we plot the log I0 against 1=T , and from the slope of the linear fitting (m = 3607:9K) the value of the contact potential is V0 = 0:31V . This value of the contact potential is directly related to the value of the gap of the semiconductor

---

The value needed, using a contra-wound approach is 138.6 pF. One can derive, from data values in Figs. 1 - 4 in Article 28, that the Q of the common 365 pF, non-ceramic insulated variable capacitor (capacitor B), at 1710 kHz comes out as follows:

- If one uses a conventional 250 uH inductor tuned by 20 pF stray capacity with 14.65 pF more from the variable capacitor, the capacitor Q comes out at about 460.
- If one uses a contra-wound inductor that has 62.5 uH inductance with the two windings in parallel, tuned by 20 pF stray capacity with 118.6 pF more from variable capacitor B, the Q comes out at about 1770, 3.5 times as great! This translates directly to greater sensitivity and selectivity when using the commonly available 365 pF capacitor.

From Fig. 3 in Article #24 we can see that, at 1710 kHz, the Q of capacitor A, a ceramic-insulated, with silver plated plates capacitor manufactured by Radio Condenser Corporation, or its successor TRW, has a Q of 9800. This is much higher than that of capacitor B when using a conventional 250 uH inductor. Changing to a contra-wound coil while using the easily available capacitor B goes a long way toward a goal of reducing the effect of the variable capacitor on tank Q and loss at the high end of the band.

Less selectivity variation and less insertion power loss: Conventional inductor: The 3 dB down RF bandwidth will vary from 3.69 kHz at 520 kHz to 39.9 kHz at 1710 kHz, a variation of 11.6 times . Contra-wound inductor: The 3 dB down RF bandwidth will vary from 3.69 kHz at 520 kHz to 12.15 kHz at 943 kHz in the low band, and from 3.04 kHz at 943 kHz to 9.99 kHz at 1710 kHz in the high band, an overall variation of 4.00 times. This is about 1/4 of the variation

See 'The contra-wound tank inductor' in Part 3 of Article #26 and the paragraph after Figs. 2 and 3 in Article #29 for descriptions of two different contra-wound configurations.

Discussion:

Let us divide the BC band geometrically into two halves: This gives us 520-943 kHz for the low band and 943-1710 kHz as the high band. Assume, for ease of understanding, that the tank inductor for the conventional approach has an inductance of 250 uH.

Conventional 250 uH inductor: The whole BC band of 520-1710 kHz can be tuned by a capacitance varying from 374.7 to 34.65 pF.

Contra-wound 250/62.5 uH inductor: The low band of 520-943 kHz can be tuned, using the 250 uH series connection, by a capacitance varying from 374.7 to 113.94 pF. The high band of 943-1710 can be tuned, using the 62.5 pF parallel connection, by a capacitance varying from 455.76 to 138.60 pF.

For the purposes of this discussion, let us assume that antenna matching (see Part 2 of Article #22) is always adjusted to reflect a fixed shunt resistance of 230k ohms for driving the diode, over the full BC band. 230k ohms is also the RF input resistance of an ITT FO-215 germanium diode when fed a signal power well below its linear-to-square law crossover-point (see Article #10, points 1, 2 and 3 below Fig.1 in Article #15, Article 17A and Article #22). This setting approximates that for minimum insertion power loss (see Article #28).

Reduction of insertion power loss at the high end of the BC band (1720 kHz): The total tuning capacitance needed when tuning a conventional 250 uH inductor to 1710 kHz is 39.9 pF.

through eq. (2.6), which tells us that the value of the gap is given by the contact potential up to an additive term depending on the temperature, the doping, and the density of states. Therefore we can assume that the values of the gap and contact potential must be within the same order of magnitude, as it is the case since for Germanium Eg = 0:67eV .

As in the case of the ideality factor, here we also have to consider the uncertainty in the saturation current I0. The results for V = ¡5V could be affected by other effects which produce uncontroled deviations of the values of the contact potential and gap.

7 Conclusions

We have studied the behavior of a Germanium p-n junction, developing the simplest theory to explain it, namely, ideal behavior of an abrupt junction with low level injection current. We also outlined several corrections to this theory, which must be considered when analyzing the experimental data.

The I-V characteristic for the germanium diode was presented for room temperature (t = 20dC) and t = 80dC, showing the expected qualitative dependence with the applied potential, exponential increment with forward bias, and small values quite independent of the reverse bias.

A further study of the forward bias regime was presented to try to fit the different mechanisms involved in the transport of carriers through the junction. It was found that the low voltage region is consistent with the ideal behavior plus, possibly, generation within the depletion region. The high voltage region is consistent with a high level injection current mechanism and ohmic losses.

The dependence on temperature of the reverse saturation current I0 (V = ¡5V) yields a value for the contact potential generated by the junction, which is directly related to the energy gap of germanium. It was found that both values are within an order of magnitude, and the doping density and density of states account for the difference between them.

Acknowledgments

I would like to thank Rodrigo Ruiz Campo for his enthusiastic view of laboratory work, and very fruitful discussions. I also want to acknowledge discussions with Susana Fernandez Robledo.

12. The effects from using the contra-wound dual-value inductor configuration in crystal sets as compared to using a conventionally wound inductor, both using capacitive tuning

Some quick facts:

- Crystal sets using a conventional single-valued tank coil usually suffer from poor selectivity and sensitivity at the high end of the BC band.
- Use of both connections of a contra-wound dual-value inductor enables the achievement of much higher selectivity and sensitivity at the high end of the BC band (series connection for the low half and parallel for the high half of the BC band).
- There will be some small reduction in tank Q in the lower half of the BC band. One reason is that distributed capacity is greater in the series-connected contra-coil than in the conventional solenoid (the close-space adjacent ends of the contra-coil windings have 1/2 the tank voltage across them). Tank Q at the high end of the BC band is noticeably improved.
- It is assumed that comparisons between conventional and contra-wound inductors use coils having the same physical dimensions and wire specifications. The inductance of the conventional solenoid is assumed to be about the same as that of the series-connected contra-coil.

A fact of interest that some may not know is this: The AC resistance of carbon composition resistors, and film resistors, to a much lesser degree, decrease with increasing frequency (the Boella Effect). This effect is strongest in high value resistors, above, say, 22k ohms and above 50 MHz (film resistors). The effect is noticeable in 500k and 1 meg units at lower frequencies. Low value resistors having short leads and resistances in the mid 10s to mid hundreds of ohms are quite free of this effect up through many hundreds of MHz. A typical graph of the ratio of AC-to-DC resistance vs frequency, of various values of conventional commercial axial-lead carbon film type resistors, taken from a Brell Components catalog is .

DIODES

Dick Kleijer crystal-radio.eu

http://www.crystal-radio.eu/endiodes.htm

Which diode can I use best in my crystal receiver?

Maybe you think a diode with a voltage drop as low as possible, then also small signals at the detector circuit are detected. But diodes with a low voltage drop, also have a high reverse current (leaking current), this will load the detector circuit heavier, the Q of the detector circuit reduces, and with that also the voltage across the LC circuit. At a lower input voltage the diode will give much more losses, and it can happen that despite the lower voltage drop of the diode, you have less voltage at the load resistor. Besides that, reduction of circuit Q will also gives a less selective receiver.

For every 20 mV less voltage drop, the reverse current will approximately double.

Germanium, silicon, en schottky diodes. Depending on the material they are made from, we can distinguish germanium diodes, silicon diodes and schottky diodes. There are some more types, which are not discussed here.

Silicon diodes have the highest voltage drop (about 0.5 Volt) and are for this reason not very useable for crystal receivers. Unless we use a small DC bias current, which brings the diode already a little bit in conduction.

Germanium diodes have a low voltage drop (about 0.1 - 0.2 Volt) and are often used in crystal receivers. The properties like voltage drop and reverse current can vary a lot between two germanium diodes of the same type. In practice we can best test several germanium diodes in our receiver and then choose the best. The diode resistance RD of germanium diodes is most times rather low, and only useable in crystal receivers with a low Q (low sensitivity and low selectivity). For high performance receivers, we can better use a suitable schottky diode.

Schottky diodes have a voltage drop of about 0.25 Volt. The differences in properties between two diodes of the same type are often small. Schottky diodes with the correct resistance RD are very useable in high quality crystal receivers.

The given voltage drop is normally measured at a forward current of about 1 mA. Also if we measure the voltage drop of a diode with a multimeter, the test current shall be about 1 mA. But also below this voltage drop the diode can conduct current, and can rectify a RF (radio frequency) signal. Only the current through the diode is then much smaller. When receiving very weak stations, the current through the diode can be e.g. only 10 nA. At such a low current, the voltage drop of the diode is also much lower then at 1 mA.

Detected voltage as function of the input voltage. If we rectify a RF signal with a diode we can distinguish two situations.

Situation 1: Rectifying in the linear region

If the input voltage is high enough (well above the voltage drop of the diode at 1 mA), the output voltage of the diode will be about proportional to the input voltage.

So double input voltage, gives about double output voltage.

The output voltage is almost equal to the peak value of the input voltage.

The power losses in the diode are in this region very low compared to the rectified power.

The brand of resistor may be guessed by examining the smoothness and shininess of its surface finish, and looking at each end of the resistor to see where the wire exits. Allen Bradley resistors look the best. They have bright color code colors and a smooth shiny finish. At the wire exit point from the body one can usually see the appearance of a small shiny ring embedded in the plastic. Actually, this is part of the lead, shaped to be the contact electrode. Stackpole resistors look next best. They have somewhat duller colors on the color code and the surface is somewhat rougher and less shiny. The wires exit cleanly from the end of the resistor, no ring is visible. The Speer resistors have the dullest color code colors and a rougher surface than the Stackpole's. They usually look as if they have been wax impregnated. At the axial exit points from the body, a small copper colored dot may be seen next to the wire lead. This is actually the end of the lead, which was folded over and back on itself to form the electrode. The IRC so-called carbon comp. resistors can be identified by the visible 'mold-flash' marks on the body and ends. The colors are good, but the body is rough. Their end surfaces are slightly convex, not planar as in the case of the other resistors.

Remember, these resistors usually made spec. when new, passed incoming inspection and standard aging tests. Unfortunately, no aging tests could be made that covered the span of many decades.

It is interesting to note that the best resistors, from a long term resistance drift point of view turn out to be the AB units. They also cost the most. The Speer units cost the least and the Stackpole's were in between.

Ohmite carbon comp resistors I have seen looked like A-B units.

- Audio transformers having too low a shunt inductance will reduce bass response. When using magnetic headphone elements, this can be partially compensated for by connecting the transformer to the headphones using a suitable capacitor.
- Refer to Articles #2, #3,#5 and #14 for more info. Consider the 'Ulti-Match' by Steve Bringhurst at http://www.crystalradio.net/sound-powered/matching/index.html.

11. Long term resistance drift and frequency dependence of the AC resistance of low power resistors, etc:

From my early experience in the manufacturer of Blonder-Tongue products, the following is some insight relative to run-of -the-mill commercial carbon-composition resistors that we used:

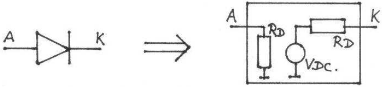
The process used by the resistor manufacturer is an important factor in the determination of long term resistance drift. Allen-Bradley (A-B) used their 'hot-mold' process, producing a more dense product then did the other manufacturers, as far as I know. The value of this carbon comp. resistor drifts the least, as a rule. Stackpole composition. resistors used their 'cold-mold' process and seem to drift more than do the A-B units. Composition carbon resistors mfg. by the Speer company, using their 'cold-mold' process drift more than the Stackpole resistors, as a rule. The IRC resistors that look like carbon comp. units actually are made by another process. They are called metallized resistors. My impression is that their drift is similar to the of Stackpole resistors. I have found that the IRC resistors usually generate much more low frequency noise when passing a DC current than the others. It seems, as a general rule, that the high value resistors drift more, over time, than the low value ones.

Situation 2: Recifying in the square law region

If the input voltage is low, lower then the voltage drop of the diode (at 1 mA) then the situation is completely different.
The input of the diode behaves for the RF signal like a resistor with value RD.
The output of the diode behaves like a DC voltage source in series with a resistor, the value of this resistor is also equal to RD.
The value of the DC voltage source is square law related to the amplitude of the RF input signal.
So double input voltage, gives 4 times as much detected DC voltage at the output
In the square law region the output voltage of the diode will be much lower then the input voltage, the diode gives much power loss between input and output.

The lower the input voltage, the higher the losses.
The higher the input voltage, the lower the diode losses.
When further increasing the diode input voltage, we gradually come into the linear detection region.
When receiving weak stations, detection takes place in the square law region.

Between the linear and square law region, there is a region not linear, and not square law but somewhere in between.
This region is not discussed here.



Equivalent circuit of a diode at low input voltages

Via this link you find a measurement on several schottky diodes, which shows detection in the square law region takes place at input voltages below 200 mVpp.

Diode resistance RD.

At zero voltage, diodes have a certain resistance.

This resistance at zero Volt we call RD.

The lower the reverse leaking current of the diode, the higher resistance RD.
When detecting small signals (in the square law region) the input of the diode also behaves like a resistor with value RD.

But how do we know the RD of a diode?

We can calculate it with the formula:
formula 1: RD = 0.000086171 x n x TK / Is
RD = diode resistance at zero Volt (unit: Ohm)
n = ideality factor, the lower this factor the better, between 1.0 and 1.1 is a very good value.
TK = temperature in Kelvin (= temperature in °C + 273)
Is = saturation current (unit: A)
x = multiply

The values of n and Is can (sometimes) be found in the diode datasheet.

In the following table some types of schottky diodes, with the values for n, Is and Rd, the maximum reverse voltage and the diode capacitance at zero voltage.

Here are some practical experimental ways to vary the audio source resistance of a crystal radio set when receiving weak-to-medium-strength signals. A medium strength signal is defined as one at the crossover point between linear to square law operation (LSLCP). See the graphs in Article #15A.

- Change the diode to one having a lower saturation current, such as from a germanium diode (1N34A) to one or several paralleled Schottky diodes such as the Agilent 5082-2835. Schottky diodes described as "zero bias detectors' have a high saturation current and are not suitable for most crystal radio set use. Schottky diodes described as "power rectifiers' usually have a high saturation current as well as a high junction capacitance. A high diode junction capacitance will reduce treble response. Too large a diode RF bypass capacitor in the crystal radio set can also reduce treble response. A side benefit from a change to a diode having a lower saturation current value, on some crystal radio sets is an increase in selectivity. This is because the RF load resistance presented by the diode to the tank is raised when the diode saturation current value is reduced. This reduced loading raises the tank Q and hence, increases selectivity.
- Use an audio transformer between the detector output and the phones. A smaller step-down transformer impedance transformation ratio will raise the transformed diode source resistance seen by the phones. A larger ratio will decrease it.
- If the headphone elements are in series, reconnecting them in parallel will reduce their impedance to 1/4 the previous value. This has the same effect as increasing the effective source resistance driving the headphones. If they are in parallel, series connecting them has the effect of decreasing the effective source resistance.

#9082 are suitable and are available from various distributors such as Alltronics, Digi-Key, etc.

Surface mount diodes manufactured using the SOT-23 package can be handled using Surfboard #6103. Diodes using the smaller SOT-323 package can be handled using Surfboard #330003. This includes many Agilent surface mount diodes useful in crystal radio sets. Packages containing multiple diodes exist that use the SOT-363 six lead package. They can be handled using Surfboard #330006. Agilent produces many of their Schottky diodes in dual, triple and quad form in the SOT-363 package.

It is recommended that anyone considering using Surfboards visit the above mentioned Website and read "Application Notes" and the "How-to Index".

10. How to modify the tone quality delivered by headphones: It is interesting to note that driving magnetic headphone elements with a high source resistance tends to improve the treble and reduce the bass response, compared to the response when the AC source resistance matches the effective impedance of the elements. Conversely, driving the headphones elements from a low resistance source tends to roll off the treble, and relatively speaking, improve the bass. With piezo ceramic or crystal elements, a high source resistance tends to reduce the treble and improve the bass response, compared to the response where the source resistance matches the effective impedance of the elements. A low source resistance tends to reduce the bass and emphasize the treble. Some piezo elements sound scratchy. This condition can be minimized by driving the elements from a lower resistance source.

type diode	n	Is at 25 ºC	RD at 25 ºC	maximum reverse voltage	capacitance	
5082-2835	1.08	22 nA	1260 kΩ	8 Volt	1 pF	datasheet
BAT85	?	?	± 200 kΩ ??	30 Volt	10 pF	datasheet
HSMS 2820	1.08	22 nA	1260 kΩ	15 Volt	1 pF	datasheet
HSMS 2850	1.06	3000 nA	9.07 kΩ	2 Volt	0.3 pF	datasheet
HSMS 2860	1.10	38 nA	743 kΩ	4 Volt	0.3 pF	datasheet

To decrease the value RD, we can connect more diodes in parallel, with two the same diodes parallel the value of RD shall halve.
With 3 diodes parallel, the value of RD shall be divided by 3 etc..

Diode resistance when using bias current.

We can decrease the value of RD by sending a small DC bias current (e.g. 0.1 uA) in forward direction through the diode.
The higher the bias current, the lower RD will be.

With the following formula we can calculate the diode resistance RD, when we make use of a DC bias current.

Formula 2: RD = 0.000086171 x n x TK /(Ib + Is)

RD= diode resistance at certain DC bias current Ib (unit: Ohm)
n= ideality factor of the diode
TK = Temperature in Kelvin (= temperature in ºC + 273)
Ib= DC bias current through the diode in A
Is =saturation current of the diode in A

A diode with a certain RD value at a certain bias current, gives the same receiving performance as a diode without bias current with the same RD.

Influence of temperature on "saturation current: Is"

The saturation current (Is-value) is strongly depending on temperature.
A temperature increase of 1 ºC will increase the Is value by about 7 %.
In datasheets, the Is value is most times given at 25 ºC.
If the diode temperature is not 25 ºC, but another value "T", then we must multiply Is with a factor 1.07^(T-25).
T = diode temperature
^ = raise to the power of

Ideality factor n

The ideality factor n of a diode indicates how good the diode performs with regard to an ideal diode.
A (not existing) ideal diode has a value of n=1.
At low input signals, the maximum available detected output power is proportional to 1/n.
So doubling the n will halve the output power (this only applies at weak signals).

signals, each of power P/2 and that there will be four output components, as stated above. They are:

- •The two second harmonic components (both of the same frequency and phase).
- •The sum frequency component (f1+f2) Hz, which will be of the same frequency and phase as the second harmonic components since f1=f2.
- •The difference frequency component (f1-f2) at a frequency of zero Hz.
- •If we filter the harmonic and sum components as well as the two original signals from the output, only the zero Hz signal will remain; and we call it the detected DC output.

A diode detector can be thought of as a "Black Box". If the DC output impedance of the detector is matched to its load resistor and the AC signal power source of P Watts 'available power' is impedance matched to the input AC impedance of a diode detector, the DC output power can closely approach the 'available power' from the AC source. This gives us another way to look at a detector. It can be considered to be a "Black Box" that changes incident AC power of frequency "f" Hz into output power of frequency zero Hz (DC). This is the detected DC output.

9. Using surface mount components in crystal radio sets:
A convenient way to connect to the tiny leads of small surface-mount diode and IC devices is to first solder them to a "Surfboard". Pigtail leads can them be soldered through holes drilled in the Surfboard conducting races for connection to a circuit.
A surface mount device such as the OPA-349 integrated circuit (Eight lead SOIC package) can be soldered to a surfboard such as that manufactured by Capital Advanced Technologies (http://www.capitaladvanced.com). Their Surfboards #9081 or

voltage (remember the equivalent voltage is 3 times the original source internal voltage). The 1/2 comes from the 2:1 voltage division between the resistance of the equivalent source of 90,000 Ohms and the detector input resistance of 90,000 Ohms. The ratio of the new detector voltage to the old is: 3 times 1/2 divided by 0.9 = 1.67 times. This equates to a 4.44 dB increase in power applied to the detector. If the input signal to the detector is so weak that the detector is operating in the square-law region, the audio output power will increase by 8.88 dB! This is about a doubling of volume.

7. Caution to observe when cutting the leads of a glass Agilent 5082-2835 Schottky diode (or any other glass diode): When it is necessary to cut the leads of a glass packaged diode close to the glass body, use a tool that gives a scissors type of cut. Diagonal cutters give a sudden physical shock to the diode that can damage its electrical performance. This physical shock is greater than one might expect because of the use of plated steel instead of more ductile copper wire. Steel is used, in part, because of its lower heat conductivity, to reduce the possibility of heat damage during soldering.

8. Several different ways to look at a diode detector: A diode detector can be thought of as a mixer, if one thinks of its input signal as consisting of two identical signals of equal power, in phase with each other. It is well known that if a common AM mixer is fed with two signals of frequencies f1 and f2 Hz, most of the output it generates will consist of the second harmonic of each signal and two more signals at other frequencies. One is at the sum frequency (f1+f2) Hz and one at the difference frequency (f1-f2). Additional mixer products can be generated, but they will be weaker than those mentioned and will be neglected in this discussion. In the case of an AM diode detector, we may consider that its input signal of power P Watts is in reality the sum of two equal in-phase

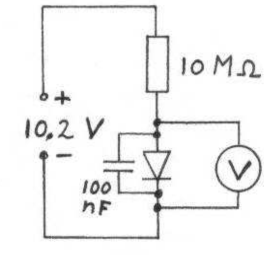
Diode capacitance

Between the two connections of the diode there will be a certain capacitance (capacitor value), when this capacitance is fairly high (e.g. 10 pF) the tuning range at high frequencies is limited.
At increasing reverse voltage across the diode the capacitance will reduce, also the detected voltage in a crystal receiver is such a reverse voltage.

Through this, the frequency of the circuit can shift upwards when receiving strong signals.
On the next page: experiments with a detector unit you find in table 3 a measurement about the frequency shift.

Measuring the Is value of a diode.

We can measure the Is value of a diode as follows:
Send a small current through the diode, the value of this current (ID) must be about 1 μA.
Measure the voltage across the diode (VD).



Circuit diagram for measuring the Is value of a diode.
The voltage across the diode is about 0.2 Volt.
The voltage across the resistor is about 10 Volts, so the current is about 1 μA.
The voltmeter must have a resistance of at least 10 MΩ.
The 100 nF capacitor reduces the influence of radio signals and hum on the measurement.

Calculate Is with the formula:

formula 3: Is = ID / (e^ (VD /(0.0257xn))-1)
Is = saturation current of the diode in nA
ID = current through the diode in nA, (1 μA = 1000 nA)
e = base of the natural logarithms, this is about 2.718
^ = raise to the power of
VD = voltage across the diode in Volt
n = ideality factor of the diode, if you don't know this value, take for instance: n= 1.08

An impedance-matched condition occurs when the resistance component of the input impedance of the crystal radio set equals the source resistance component of the impedance of the antenna-ground system. Also, the reactive (inductive or capacitive) component of the impedance of the antenna-ground system must see an opposite reactive (capacitive or inductive) impedance in order to be canceled out. In the impedance-matched condition, all of the maximum available power (See section on "Maximum Available Power" above) intercepted by the antenna-ground system is made available for use in the crystal radio set and none is reflected back towards the antenna to be lost.

Now we are at the point where confusion often exists: The voltage concept vs. the power concept. Let's assume that the diode detector has a RF input resistance of 90,000 Ohms. Assume that the antenna-loaded resonant resistance of the tuned circuit driving it is 10,000 Ohms. If one uses voltage concepts only, one might think that this represents a low loss condition. NOT SO! After all, 9/10 of the actual source voltage is actually applied to the detector. If one impedance matches the 10k ohm source RF resistance to the diode 90k ohm RF resistance via RF impedance step-up transformation (maybe connecting the antenna to a tap on the tuned circuit, and leaving the diode on the top), good things happen. (We will assume here that, in the impedance transformation to follow, the ratio of loaded-to-unloaded Q of the tuned circuits is not changed.) For an impedance match, the tuned circuit resonant resistance should be transformed up by 9 times. If this was done by a separate transformer (for ease of understanding) it would have a turns ratio of 1:3, stepping up the equivalent source voltage by 3 times and changing the equivalent source resistance to 90,000 Ohms. What now? Before matching, the diode got 9/10 of the source voltage applied to it. Now it gets 1/2 the new equivalent source and spreads out as it goes away from the antenna. One can prove that power is radiated by substituting a LED diode for the regular diode, getting physically close enough to the station and then tuning it in. The LED will light up (give off light power), showing that some power is being broadcast and that it can be picked up. Now back at home, if one tunes in the station one gets sound in the headphones. What activates one's hearing system is the power of the perceived sound. BTW, if one gets too much sound power in the ear for a long enough time, the power can be strong enough to break off some of the hair cells in the inner ear and reduce one's hearing sensitivity forever. The theoretical best one can do with a crystal radio set setup is the following: (1) Use an antenna-ground system to pick up as much as possible of the RF power passing through the air in its vicinity . In general, a higher antenna will pick up more power from the passing RF waves than will a lower one. (2) Convert the intelligence carrying AM sideband RF power into audio electrical power. (3) Convert the electrical audio power into sound power and get that power into the ear.

There are power losses at each of the three steps and our job is to minimize them in order to get as much of the sideband RF power passing through the vicinity of the antenna (capture area) changed into audio power for our ears. We want all of the "available power" at the antenna-ground system to be absorbed into the crystal radio set then passed on through it to our headphones as sound. However, some of it will be unavoidably lost in the RF tuned circuit. If the input impedance of the crystal radio set is not correctly matched to the impedance of the antenna, some of the RF power hitting the input to the crystal radio set will be reflected back to the antenna-ground system and be lost.

More information about measuring the Is you can find on the website of Ben Tongue , in his articles number 4 and 16.

I measured the Is value of several diodes, and calculated the diode resistance RD.
Also some European germanium types are measured.
Several diodes are measured of the type OA95 and AA119

Diode	VD (Volt) at 1 µA	Is (nA)	RD (kΩ).
HSMS282K	0.1341	7.9	3428
HSMS282K 2 parallel	0.118	14.5	1867
HSMS286K (1 diode)	0.1116	18.3	1479
5082-2800	0.1871	1.14	23756
5082-2835	0.1464	5.04	5373
5082-2835 2 parallel	0.1289	9.5	2850
BAT 82	0.136	7.3	3710
BAT 85	0.0686	90.8	298
OA81 (germanium)	0.0225	800	34

OA95 #1 (germanium)	0.0272	600	45
OA95 #2	0.0221	821	33
OA95 #3	0.0271	604	45
OA95 #4	0.0304	502	54
AA116 (germanium)	0.0441	256	106
AA119 #1 (germanium)	0.0320	461	59
AA119 #2	0.0363	370	73
AA119 #3	0.0428	272	100

The HSMS282K is the same as the HSMS2820, only the HSMS282K has 2 equal diodes in one package.
The Is value of the HSMS282K, the HSMS286K and the 5082-2835 is lower than the value in the datasheet, this has also been noticed by other people.

Ben Tongue wrote me, that the Is value of the 5082-2835 has been reduced over the years by the manufacturer.
Also temperature has big influence, I measured at 18 ºC, in datasheets the Is value is given at 25 flC.
A increase from 18 flC to 25 flC will increase the Is by 60 %.

power (1.0^2)/Ri to equal the output power [(1.0*2*sqrt2)^2]/Ro, the input RF resistance (Ri) must equal 1/8 Ro. That is, Ri=Ro/8. This illustrates the direct interaction between the RF input resistance and output audio resistive load. At high input power levels selectivity drops substantially if the output resistive audio load value is lowered.
The audio output resistance of the detector approaches 8 times the RF source resistance driving it. This fact is seldom recognized and it may be the cause of some of the problems encountered by those experimenting with doublers.

4) Half-wave voltage doubler operating at a low input signal power level: The detector, in this case, does not operate as a peak detector, and it has significant power loss. At low input signal power levels Ri approaches (0.026*n/Is)/2 ohms and becomes independent of the value of Ro.

The audio output resistance of the detector approaches twice the axis-crossing resistance of the diode.

5) Summary: At high input power levels, and with both input and output matched, power loss in both half wave and half wave voltage doubling detectors approaches zero dB. Sound volume should be the same with either detector. At low input power levels both detectors exhibit substantial power loss. I believe, but have not proven, that at low input power levels the doubler has a higher power loss than the straight half wave detector, and should deliver less volume.

6. Some misconceptions regarding Impedance matching and Crystal Radio Sets: To understand the importance of impedance matching, one must first accept the concept of power. A radio station accepts power from the mains and converts some of it to RF power which is radiated into space. This power leaves the transmitting antenna at the speed of light

1) Conventional half-wave detector operating at a high input signal power level: The detector, in this case, operates as a peak detector. Since it is a passive device, its output power will approximately equal its input power, under impedance-matched conditions. The output DC voltage will approach sqrt2 times the input RMS voltage, since the peak value of a sine wave is sqrt2 times its RMS value. For the input power, (1.0^2)/Ri, to equal the output power, [(1.0*sqrt2)^2]/Ro, the input RF resistance (Ri) must equal 1/2 Ro. That is, Ri=Ro/2. This illustrates the direct interaction between the RF input resistance and output audio resistive load. At high input power levels selectivity drops when the resistive audio output load value is lowered. The audio output resistance of the detector approaches 2 times the RF source resistance driving it. If the diode were an ideal diode, the word "approximately" should be eliminated, and "approaches" should be changed to "becomes" .

2) Conventional half-wave detector operating at a low input signal power level: The detector, in this case, does not operate as a peak detector, and exhibits significant power loss. At low input signal power levels Ri approaches 0.026*n/Is ohms (diode axis-crossing resistance) and becomes independent of the value of Ro.

The audio output resistance of the detector approaches the same value as the axis-crossing resistance (see above).

3) Half-wave voltage doubling detector operating at a high input signal power level: The detector, in this case, operates as a peak detector. Since it is a passive device, its output power will approximately equal its input power, under impedance-matched conditions. The output DC voltage will approach 2.0*sqrt2 times the input RMS voltage, since the peak of a 1.0 volt RMS sine wave is sqrt2 times its RMS value. For the input

Diode forward voltage drop:
David Knight

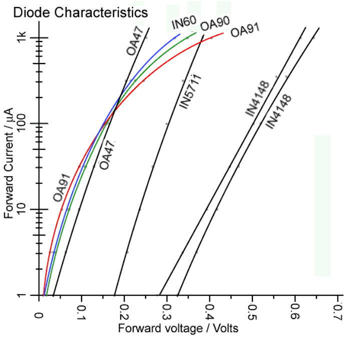
http://www.g3ynh.info/circuits/Diode_det.pdf

All of the diode detectors described above have at least one diode forward voltage-drop in the path to the measuring device. The diode forward voltage drop, Vf, varies approximately in proportion to the logarithm of the current, If, passing through the diode, and also depends on the temperature of the diode junction. For many types of diode, this behaviour is described to a good approximation by a modified form of the Ebers-Moll equation[12]:

$$Vf = m (kT/q) \ln[(If / Is) +1]$$

where k is Boltzmann's constant (1.380662 10 Joules/Kelvin) , q is the charge of an electron (1.6021892 10 Coulomb), and T is the temperature in Kelvin, i.e., the absolute temperature (flC+273.16). The factor kT/q is sometimes given the symbol VT, and has a value of 25.3mV at 20flC. "m" is a dimensionless correction factor between 1 and 2. "ln" is the natural logarithm (Loge). Is is the junction reverse saturation leakage current.

For small-signal rectifier voltmeters, diodes should be chosen for low forward voltage drop and low junction capacitance. Most sources of information now maintain that the best diodes in this respect are silicon Schottky-barrier (i.e., silicon-metal junction) diodes, such as the 1N5711 (Agilent 5082-2800) [18]; and so to investigate this matter, the forward voltage drop versus current characteristics of a variety of small signal diodes were measured. The results are shown in the graph below:



The 1N4148 is a silicon P-N junction diode. The 1N5711 is a silicon Schottky diode. The OA47 is an archaic germanium gold-bonded diode, and the rest are germanium point-contact diodes. Two 1N4148 diodes from different manufacturers were measured merely to illustrate the point that silicon P-N diodes have the highest forward voltage drop and are therefore a poor choice for low voltage detectors. The 1N5711 curve is the average of results from four diodes, all from the same batch, which had practically identical characteristics. The OA47 curve is the average for four diodes from two manufacturers, all having similar characteristics. The OA90, OA91, and 1N60 curves are from single examples, and are therefore not necessarily representative of the type. All data were recorded at an ambient temperature of 21flC.

signals are received, since both input and output ports become impedance matched.

Here is an interesting conceptual view of a high signal level diode detector circuit: Assume that it is driven with a sufficiently high level sine wave voltage so it operates in its peak detection mode, and is loaded with a parallel RC of a sufficiently long time const ant. This detector may be thought of as a low loss impedance transformer with a two-to-one impedance step up from input to output, BUT having an AC input and a DC output, instead of the usual AC input and output. The DC output power will approximately equal the AC input power and the DC output voltage will be about sqrt 2 times the RMS AC input voltage.

5A. A comparison of conventional half-wave and half-wave voltage-doubling detectors: Here is some info that may be of interest re conventional half-wave detectors vs. voltage doubling half-wave detectors when each is terminated with an output load of Ro. For illustration purposes we will assume the input voltage to the detector to be 1.0 volt RMS. The RF input resistance of the detector will be designated as Ri. All diodes have the same Is and n. It is assumed that good diodes such as a 5082-2835 Schottky, ITT FO-215 germanium or other are used. The info relates to the RF input resistance of detectors (it has a large effect upon selectivity) and their output audio resistance. See Point 4 in this Article for info on diode Is and n.

A high input power level is defined as one that is high compared to that at the LSLCP of the detector. A low input power level is defined as on that is low compared to that at the LSLCP of the detector. See "Quick Summary" in Article #15 for info on LSLCP.

resistance. Further, since the detector is now a peak detector, the DC output voltage is the "square root of 2" times larger than of the applied input RF RMS voltage. (It's equal to the peak value of that voltage). These existence of these relationships is necessary so that in an ideal peak detector, the output power will equal the input power (No free lunch). Summary: Output DC voltage equals sqrt2 times input RMS voltage. Since the output power must equal the input power, and power equals voltage squared divided by resistance, the output load resistance must equal two times the source resistance, assuming impedance matched conditions prevail. If we were to adjust the input source resistance to, say 495k ohms (reduce it by sqrt2) and the output load resistance to 990k ohms (increase it by sqrt2) by changing the input and output impedance transformation ratios, the insertion loss would become even lower than before the change and the input and output impedance matches would be very much improved (remember we are now dealing with high signal levels).

A good compromise impedance match, from one point of view, occurs if one sets the RF source resistance to 0.794*Rd and the audio load resistance to 1.26*Rd. With this setup, theoretically, the impedance match at both input and output remains very good over the range of signals from barely readable to strong enough to produce close to peak detection. A measure of impedance match is "Voltage Reflection Coefficient", and in this case it is always better than 18 dB (VSWR better than 1.3). Excess insertion loss is less than 1/3 dB and selectivity is largely independent of signal level. Information presented in Article #28 shows that, if the diode load resistance is made equal to Rd and the RF source resistance is made equal to Rd/2, the weak signal output of the detector will be about 2 dB greater than if both ports are impedance-matched! There is little benefit when strong

---

The data indicate that the IN4148, the 1N5711, and the OA47, all obey a logarithmic V/I relationship rather well, whereas the germanium point-contact characteristics show considerable curvature due to high internal resistance. With regard to the forward drop however, the germanium diodes are all superior to the IN5711 in the 1-100 A range, and the preference for the latter may merely reflect the fact that many semiconductor manufacturers can no longer fabricate germanium. Silicon Schottky diodes, such as the 1N5711 and 1N6263, being essentially UHF devices, have better high-frequency performance than germanium diodes, but germanium diodes work well at VHF and are therefore perfectly adequate for HF applications. Among the germanium diodes, there is little difference between the gold-bonded and standard varieties in the 1 to 100 A range, but the OA47 is the best choice for currents up to 1mA. We should observe however, that detector diodes only conduct on the peaks of the applied waveform, and so the instantaneous current is much higher than the average current, the difference being about an order of magnitude. Therefore, in selecting diodes for average currents in the region of 1 - 100 A, we should consider the steady-state voltage drop in the region 10 A - 1mA; in which case the germanium gold-bonded diode offers the lowest forward-drop without contest. Note however, that one of the consequences of the Ebers-Moll equation is that low forward voltage-drop is associated with high reverse leakage current. If reverse leakage is an issue, then silicon Schottky diodes are to be preferred. To put this issue in perspective however, the reverse leakage current of an OA47 diode was measured as follows:

Vr /Volts	1.0	2.0	3.0	5.0	10.0	15.0	20.0
Ir /uA	1.1	1.3	1.4	2.1	4.1	6.3	8.8

The leakage current is approximately linear in the 5-20V range and may be modelled by assuming a resistor of about 2M in parallel with the diode. Such a defect has little effect on the operation of a detector loaded with a 10-100K resistor. Some final points in favour of the silicon Schottky diodes however, are that germanium diodes show a wider spread of characteristics, and that the OA47 is obsolescent. Hence the Schottky diodes are definitely preferable in applications requiring diode matching, precise calibration, or availability through normal commercial channels. The 1N5711 in particular also, has a very high reverse breakdown voltage for a device of its class, its Vr max of 70V making it suitable for half-wave detectors of up to 24.7V DC ouput. An OA47 half-wave detector has a maximum DC output of 10.6V if Vr max is not to be exceeded.

---

having 3 dB less potential weak signal output than one of the diodes by itself.

5. Explanation of why, in a diode detector, and by how much, the RF input resistance and audio output resistances change as a function of input signal power. Consider first, a diode detector that is well impedance-matched both at its input and its output when driven by a very low power RF input signal. There will then exist an appreciable power loss in the detector. (The audio output power will be appreciably less than the input power.). The input and output impedances of the detector will approximately equal each other and approach: Rd = 0.026*n/Is. See part 3 above for a definition of terms. For this illustration, let the diode have an Is of 38 nA and an n of 1.02. Rd will be 700k Ohms. The well impedance-matched condition will hold if the input power is raised from a low value, but only up to a point. After that , the match will start to deteriorate. At an input power about 15 dB above that of the square-law-linear crossover point, the match will have deteriorated to a VSWR of about 1.5:1 (VSWR = Voltage Standing Wave Ratio.). A further increase of input signal power will result in a further increase of VSWR. This means that the input and output resistances of the detector have changed from their previously matched values.

The input resistance of the diode detector decreased from the value obtained in the well impedance matched low power level situation. The output resistance increased. The reason for this change is that a new law now governs input and output resistance when a diode detector is operated at a high enough power level to result in a low detector insertion power loss. It now operates as a peak detector. The rule here is that the CW RF input resistance of a diode peak detector approaches ½ the value of its output load resistance. Also, the audio output resistance approaches 2 times the value of the input AC source crystal radio set operation, but varies with diode current in silicon pn junction and germanium point contact diodes. A way of thinking about n is to consider it as a factor that effectively reduces the applied signal voltage to a diode detector compared to the case of using an ideal diode having an n of 1.0. Less applied signal, of course, results in less detected output.

Here are a few bits of information relative to diodes:
Typically, if a diode is biased at 0.0282*n volts in the forward direction, it will pass a current of 2 times its Is. If it is biased at 0.0182*n volts in the reverse direction, it will pass a current of 0.5 times its Is. If a diode is biased at 0.0616*n volts in the forward direction, it will pass a current of 10 times its Is. If it is biased at -0.0592*n volts, it will pass a current of -0.9 times its Is. These values are predicted from the classic Shockley equation. In the real world, reverse current can depart substantially from values predicted by the equation because of effects not modeled (the reverse current becomes higher). Gold bonded germanium diodes usually depart somewhat from the predicted values when operated in the forward direction. The effect appears as an increase of Is when measurements are made at currents above about 6 times the low-current Is.

Values of Is and n determine the location of the apparent 'knee" on a linear graph of the diode forward current vs. forward voltage. See Article #7. An easy way to estimate the approximate value of Is can be found in Article #4, section 2. A method of measuring Is and n is given in Article #16.

If one connects two identical diodes in parallel, the combo will behave as a single diode having twice the Is, and the same n as one of them. If one connects two identical diodes in series, the combo will behave as a single diode having twice the n and the same Is as one of them. This connection results in a diode

* max.
** a very non-linear resistor pretending to be a diode - best avoided!

6-8a. Thermionic diodes:
Given that semiconductor diodes are imperfect, some readers may wonder if thermionic diodes (valves) are capable of better performance. The answer however (avoiding expletives) is an an unequivocal 'no!'. The forward voltage of an indirectly heated valve diode in the low-current (space-charge limited) regime (according to Terman [20]) is given by the expression:

$$V_f = [\sqrt[3]{(I_f^2 / k)}] - V_c$$

where k is a constant determined by the geometry of the diode and Vc is called the contact potential, by analogy with the potential developed by a thermocouple. The diode contact potential arises because some of the electrons ejected from the cathode arrive at the anode even when there is no bias, and so the anode becomes negatively charged. This means that the diode must be reverse biased in order to prevent it from conducting, and the amount of bias required varies with the heater temperature and the age of the valve. In precision measurement terms, the contact potential is enormous. A sample of eight double-diode valves of type EB91 (6AL5) showed contact potentials ranging from 0.48 to 0.96V (with a mean of 0.73V) when measured using a voltmeter with 10M input resistance and a stabilised 6.30V DC heater supply (sensible measurement was impossible using a filament transformer connected to the domestic mains supply). A 100 A moving coil meter with an internal resistance of 980 was connected across a diode having an open-circuit contact potential of 0.74V, and registered a zero-bias current of 70 A, i.e., the diode gave a DC output of 4.8 W due to the thermal current. When the meter was padded to 10K , to simulate the diode loading in a realistic detector circuit, the zero-bias current was 22 A, i.e., 22% of full-scale deflection. We may safely conclude that thermionic diodes have no merit whatsoever in small-signal measuring applications, even if they do glow attractively in the dark.

(Ed note: thermionic diodes were the original diode detectors and can STILL make an interesting radio.)

increase in reverse current at a specified voltage. These diodes are called Zener diodes.

Diode Saturation Current is a very important SPICE parameter that, along with the diode Ideality Factor, n determines the actual diode current when it is forward biased by at particular DC Voltage. Id=Is*(e^(Vd/(0.026*n)-1) at room temperature. This expression ignores the effect of the parasitic series resistance of the diode because it has little effect on the operation of crystal radio sets at the low currents usually encountered. Here Id is the diode current, e is the base of the natural logarithms (2.7183...), ^ means raise the preceding symbol to the power of the expression that follows (Sometimes e^ is written 'exp'), * means multiply the preceding and following symbols, VD is the voltage across the diode and n equals the "Ideality factor" of the diode. At low signal levels, most detector diodes have an n of between 1.05 and 1.2). The lower the value of n, the higher will be the weak signal sensitivity. One can see that Is is a scaling factor for the actual curve generated by the factor (e^(VD/(0.026*n)-1).

Diode ideality factor (n): The value of n affects the low signal level sensitivity of a diode detector and its RF and audio resistance values. n can vary between 1.0 and 2.0. The higher the value of n, the worse the low signal level detector sensitivity. The low signal level RF and audio resistances of a diode detector vary directly with the value of n. Schottky diodes usually have a value of n between 1.03 and 1.10. Good germanium diodes have an n of about 1.07 to 1.14 when detecting weak signals. Silicon p-n junction diodes such as the 1N914 have values of n of about 1.8 at low currents and therefore have a lower potential sensitivity as diode detectors than Schottky and germanium point contact diodes. The value of n in Schottky diodes seems to be approximately constant over the full range of currents and voltages encountered in source, so we can say we have a 'no loss' situation. Now, assume that a transformer or other two-port device is inserted between the Vs,Rs source and Ro, and that an output voltage Vo is developed across Ro. The output power is (Vo^2)/Ro. The 'insertion power loss' can now be calculated. It is: 10*log (output power)/(maximum available input power) dB. After substituting terms, the equation becomes: Insertion power loss =10*log [(Vo/Vs)^2)*(4*Rs/Ro)] dB.

If the input voltage is referred to by its peak value (Vsp) as it is in a SPICE simulation, instead of by its RMS value, the equation changes. The RMS voltage of a sine wave is equal to the peak value of that wave divided by the "square root of 2". Since the power equation squares the voltage, the equation for the 'available input power' changes to Pa = (Vsp^2)/(8Rs).

4. Diode Saturation Current and Ideality Factor: Saturation current is abbreviated as Is in all of these articles. Assume that one connects a DC voltage source to a diode with the polarity of the voltage source such as to bias the diode in the back direction. Increase the voltage from zero. If the diode obeys the classic Shockley ideal equation exactly, the current will start increasing, but the increase will flatten out to a value called the saturation current as the voltage is further increased. That is, as the voltage is increased, the current will asymptotically approach the saturation current for that diode. A real world diode has several mechanisms that cause the current to actually keep increasing somewhat and not flatten out as the back direction voltage is further increased. Diode manufacturers characterize this as reverse breakdown and specify that the back current will be less than a specified value, say 10 uA at a specified voltage, say 30 V, called the reverse breakdown voltage. BTW there are other causes of excessive reverse current that are collectively referred to as reverse bias excess leakage current. Some diodes have a sharp, controlled

A Procedure for Measuring the Saturation Current and Ideality Factor of a Diode, along with Measurements on various diodes

http://www.bentongue.com/xtalset/16MeaDio/16MeaDio.html
by Ben H. Tongue

Quick Summary: A schematic and operational instructions are given for a device for use in measuring Saturation Current and Ideality Factor of a diode. Measurements of various detector diodes are included.

The Saturation Current and Ideality Coefficient of a diode can be determined by measuring an applied junction voltage along with the associated current flow at two different voltages. These two data pairs are then substituted into the Shockley diode equation to create two simultaneous equations in Is and n, and then solved for Is and n. Since the equations include exponential functions, they can not be solved by ordinary algebra. Numerical methods must be used.

The Shockley diode equation at 25 degrees C. is: Id = Is*(exp(Vd/(0.0256789*n))-1) Amps. Id = Diode Current (amps), Is=Saturation Current (amps), Vd = Diode Voltage, n = Ideality Coefficient. The series resistance Rs of the diode is ignored because the measurement currents are so low that the voltage drop across Rs is negligible. Measurements have shown that Is and n of point contact germanium diodes can vary with current, but are relatively constant, down to very low currents, when the current is under six times Is. Silicon p-n junction diodes exhibit values of Is and n that vary with current. The values for Is and n of Schottky diodes are quite constant over the range of currents used in ordinary crystal radio set reception.

A convenient set of measuring currents is about 6*Is and 3*Is. Substituting Id = 6*Is, then Id = 3*Is into the Shockley and solving for Vd yields: For Id = 6*Is, Vd = 0.05000*n volts. For Id = 3*Is, Vd = 0.03561*n volts. The value of n will probably be between 1.0 and 1.2 for the type of diodes used in crystal radio sets, so use 1.1 in determining the applied voltage to use. Suggested voltages to use are about 0.055 and 0.039 volts, although other values may be used.

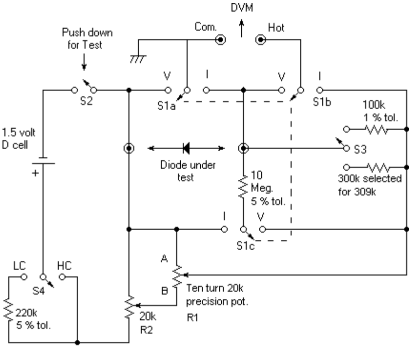

Fig. 1 - Schematic of Device for Measuring Diode Is and n.
Schematic

S1 is a triple pole double throw switch, S2 is a push button momentary-contact SPST switch. DVM is a digital voltmeter with 10 Meg input resistance having a 200 mV range setting. S3 is a range switch that enables greater precision when using a conventional 3 1/2 digit DVM. It is also used when

gain of, say 80 times, the output power is 2.5 X 80=200 mW. 2.5 mW expressed in dBm is +4 about dBm. A power gain of 80 times is about +19 dB. The output power is 4+19=+23 dBm.

3. Maximum Available Power: If one has a voltage source Vs with an inaccessible internal resistance Rs, the load resistance to which the most power (Pa) can be delivered is equal to Rs. Pa is called the 'maximum available power' from the source Vs, Rs. Any load resistance other than one equal to the source resistance, Rs, will absorb less power. This applies whether the voltage is DC or AC (RMS). The formula for power absorbed in a resistance is "voltage-squared divided by resistance". In the impedance matched condition, because of the 2 to 1 voltage division between the source resistance and load resistance, one-half of the internal voltage Vs will be lost across the internal source resistance. The other half will appear across the load resistance. The actual power available to the load will be, as indicated in the preceding relation: Pa = [(Vs/2)^2]/Rs = (Vs^2)/(4*Rs). Again, in the impedance matched condition, the total power delivered to the series combination of source and load resistance is divided up into two halves. One half is unavoidably lost in the internal source resistance. The other half is delivered as "useful output power" to the load resistance.

The 'maximum available power' approach is useful when measuring the insertion power-loss of two-port devices such as transformers, amplifiers and crystal radio sets, which may not exhibit an input or output impedance that is matched to the power source. The input impedance may be, in fact a combination of resistive and reactive components. If the Vs,Rs source is connected to a resistive load (Ro) of value equal to Rs ohms, it will receive and dissipate a power of Pa Watts. This is the maximum available power from the Vs, Rs frequencies. This is the main reason why diodes having large values for Rs and CJ perform poorly at high frequencies.

2. An explanation of the meaning and use of dB and dBm: In the acronym dBm, "d" means one-tenth. "B" refers to the Bel and is named after Alexander Graham Bell. The Bel is used to express the ratio of two powers, say (Output Power)/(Input Power). Let's call this power ratio "(pr)". Mathematically, a power ratio, expressed in Bels, is equal to the logarithm of the ratio of the two powers. B=log (pr). If the two powers are equal, the power ratio expressed in Bels is 0 B. This is because the log of one is zero. Another illustration: Assume that the power ratio is twenty. (Pr)=20. The logarithm of 20 is about 1.3. This power ratio in Bels is 1.3 B. One decibel is equal to 0.1 Bel. That is, 10 dB=1 B. If we express the two power ratios mentioned above (1 and 20) in dB, we get 0 dB and about 13 dB.

So far, we have seen that the decibel is used to express the ratio of two powers, it is not a measure of a power level itself. A convenient way to express an actual power level using dB is to use a standard implied reference power for one of the powers. dBW does this. It expresses the ratio of a power to the reference power (One Watt in this case). dBm uses a reference power of one milliwatt. A power level of, say 100 milliwatts, can be said to be a power level of +20 dBm (twenty dB above one milliwatt). Why? (100 milliwatts)/(1 milliwatt)=100. The logarithm of 100 is 2. 10 times 2 equals 20.

The convenient thing about using dB comes from a property of logarithms: The logarithm of the product of two numbers is equal to the sum of the logarithm of each number, taken separately. An illustration: If one has a power source of, say 2.5 mW and amplifies it through an amplifier having a power

measuring diodes having a high Is. R2 is used for coarse setting of the diode voltage. R1 is a ten turn precision 20k pot such as part # 594-53611203 from Mouser. It is used for fine setting of the diode voltage.

Procedure for Measuring Is and n:

1. Set S3 for 300k for diodes expected to have a low to medium Is. Set S3 to 100k if the diode is expected to have a high Is. S4 to HC and R1 to 1 about turn from point B.
2. Take Data Set #1: Set S1 to V. Push S2 and adjust R2 to obtain a reading of about 0.055 volts. Use R1 to set the voltage to the voltage desired (0.055 volts is suggested). Call this voltage V1. Set S2 to I, read the DVM and call that voltage V2.
3. Take Data set #2: Set S1 to V. Push S2 and adjust R2 to obtain a reading of about 0.039 volts. Use R1 to set the voltage to the voltage desired (0.039 is suggested). Call this voltage V3. Set S2 to I, read the DVM and call that voltage V4.
4. The diode voltage (Vd1) from Data Set #1 is V1. The diode current from Data Set #1 (Id1) is (V2/300,000)-(V1/10,000,000) or (V2/100,000)-(V1/10,000,000) Amps, depending on the setting of S3. The diode voltage (Vd2) from Data Set #2 is V3. The diode current (Id2) is (V4/300,000)-(V3/10,000,000) or (V4/100,000)-(V3/10,000,000) Amps, depending on the setting of S3.
5. The two data sets Vd1, Id1 and Vd2, Id2 must now be entered into two Shockley diode equations (shown above) in order to make two simultaneous equations in Is and n. Solving them will yield values for Is and n, measured at an average current of about 4.25 times Is.

A numerical equation solver can be used to solve the two simultaneous equations for Is and n. One is available in

MathCad. If you have MathCad 5.0 or higher, go to http://www.agilent.com/. Click your way through Communications, Communications Designer Solutions, RF and Microwave, Schottky Diodes, Library, MathCad worksheets and download the file: sch_char.mcd. Execute it in MathCad, then enter your Current and Voltage values: Id1, Vd1 and Id2, Vd2 as I2, V2, I1 and V1. Pull down 'Math' and click 'Calculate Worksheet'. The program calculates Is and n. Since most crystal set operation occurs at currents so low that there is negligible voltage drop across the diodes' parasitic series resistance, there is no need to enter any new numbers for I3, 4, 5 and V3, 4, 5 on the worksheet. The program sch_char.mcd does not work in versions of MathCad earlier than 6. If you have an earlier version of MathCad, and it has a non-linear equation solver, actual entry of the Data Set will have to take place without the convenience of the sch_char program. Those who do not have MathCad but do have Microsoft Windows Word can get an unformatted view of the default data and text provided in the MathCad program by clicking here.

There is currently available on the Web, a program from Polymath Software at: http://www.polymath-software.com/. This program has many capabilities, and among them is a nonlinear equation solving capability. A free demo copy of the latest program is available for download, but is limited to 20 uses. After that, for more usage, you have to buy it.

Some programmable pocket calculators include a nonlinear equation solver. One calculator that has one is the HP 32S Scientific Calculator. A program to solve for n and Is takes only 28 steps of program memory and is here.

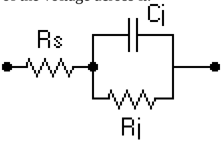
Mike Tuggle posted on 'The Crystal Set Radio Club' the following simple procedure for determining Is and n by using a

PRACTICAL CONSIDERATIONS, helpful definitions of terms and useful explanations of some concepts

Ben H Tongue

http://www.klimaco.com/HAMRADIOPAGES/xtal_how_to.htm

1. An explanation as to why some diodes that work well in the Broadcast Band cause low sensitivity and selectivity when used at Short Waves: The parasitic (approximately fixed) series resistance Rs of a diode is in series with the parallel active elements. The nonlinear active elements are the junction resistance Rj, which is a function of current through the diode, and the junction capacitance Cj, which is a function of the voltage across it.



The nonlinear junction resistance effect is what we use to get detection. The nonlinear capacitance effect is used when the diode is designed to be a voltage variable capacitor (a varactor diode).

The parasitic series resistance of some 1N34 diodes can be pretty high, and in series with the junction capacitance, make that capacitance have a rather low Q at high frequencies. This capacitance is, in a crystal radio set, effectively in parallel with the RF tank. The tank usually has a small value tuning capacitor itself, so the overall tank circuit Q is reduced at high resistive loading occurs from the real but usually neglected current passed in the back direction during the RF reverse peak voltage excursions. This causes power loss and is a cause of loss of volume. For a given Is, good germanium diodes are usually superior to Shottkys in this respect.

Best regards,

Ben
eug4not

spreadsheet. 'In lieu of an equation solver package, the Schottky parameters can be solved for by simple trial-and-error. This is easily done with an ordinary spreadsheet, like Excel or Lotus. For the two measurement points, (Id1, Vd1) and (Id2, Vd2), set up the spreadsheet to calculate: Id2[exp(Vd1/0.0257n) - 1] and, Id1[exp(Vd2/0.0257n) - 1]. Then experimentally plug in different trial values of n, until the two expressions become equal. This gives the correct value of n. Now, plug this value of n into: Is = Id1 / [exp(Vd1/0.0257n) - 1] or, Is = Id2 / [exp(Vd2/0.0257n) - 1] to get the correct value of Is.' An Excel spreadsheet constructed as Mike suggested is here. An example from data taken on an Agilent HBAT-5400 is entered, for reference, on line 2. Line 3 may be used for calculations using data from other diodes. Column H automatically calculates a value for Is each time n is changed. All one has to do is enter the values as described above in columns A through E and hit enter.

Caution: If one uses a DVM to measure the forward voltage of a diode having a high saturation current, a problem may occur. If the internal resistance of the DC source supplying the current is too high, a version of the sampling voltage waveform used in the DVM may appear at its terminals and be rectified by the diode, thus causing a false reading. One can easily check for this condition by reducing the DC source voltage to zero, thus leaving only the internal resistance of the source in parallel with the diode, connected across the terminals of the DVM. If the DVM reads more than a tenth of a millivolt or so, the problem may be said to exist. It can usually be corrected by bypassing the diode with a ceramic capacitor of between 1 and 5 nF, preferably, an NPO type. I use a 0.047 uF NPO multi-layer ceramic cap from Mouser Electronics. Connect the capacitor across the diode with very short leads, or this fix may not work.

Tips

* If the Is of the diode under test is too high, 0.055 volts will not be attainable for V1 in step 1. The solution is to set switch S3 to 100k. The calculations for diode current then become: Id1=(V2/100,000)-(V1/10,000,000) Amps and (Id2=V4/100,000)-(V3/10,000,000) Amps.

* If the voltage readings seem to unstable, try placing the measuring setup on a ground plane and connect the common lead of the DVM to it. A sheet of household aluminum can be used for the ground plane. Use shielded cable from the lead from the DVM to the test setup.

* The voltage readings are very sensitive to diode temperature. You can see this easily by grasping the diode body with thumb and forefinger and noting the change in the voltage reading when measuring V1 or V3. Don't take data until the readings stabilize. Saturation current is a strong function of junction temperature. For germanium and the usual (n-doped) Schottky diodes, a temperature increase of 10fl Celsius results in a saturation current increase of about two times. A simple rule is: For each 1fl C. increase in temperature, Is increases by 7.2%. The figures are different for zero-bias-type Schottkys. Here, a 14 degree C. (25 degree F.) change in temperature will result in approximately a two times change in Is.

* Shield glass enclosed diodes from ambient light by placing a cardboard box over the unit. Many diodes have a photo-diode response and will give an output voltage when exposed to light even if no current is applied.

Note: A simplified method of determining the Saturation Current of a diode, if the Ideality Factor is estimated in advance is shown in Section #2 of Article #4.

resonance increases as the coupling between the detector and ATU is reduced - and therefore a diode with a larger rc value is a better match. If this is the case, then for really good radios with very high Q detector tank circuits, two different diodes may give the loudest output - one when coupling is very tight, and a different one when coupling is very loose. (Any comments??)

For my radio used here, the 1N141 diode (thank you Bruce Kizerian!) seems to give about the loudest output for both tight and loose coupling at the low end of the band. But the FO-215's output is very close and has a bit better selectivity. The schottky diodes (1SS98 & 5082-2835) are seen to be useful even for my modest radio if there is plenty of signal that can be traded-off for greatly improved selectivity.

Well, that's my attempt at measuring my crystal radio's audio output. Hope it's of interest. If my measurements or methods are way off base, please let me know.

It sure is a blessing to be retired and to have the luxury of time to play.

73's, Dan

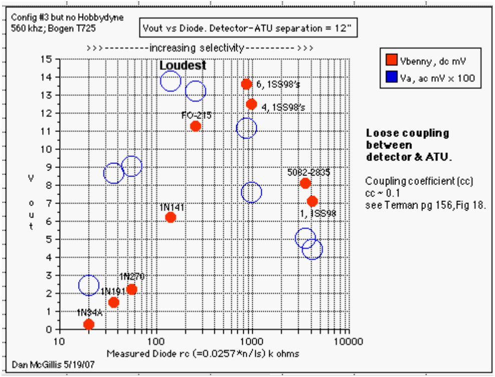
May 23, 2007
Hi Dan,

You have developed some really insightful information.

There is one thing, I believe, that is being overlooked re the low Is (high Rx) Schottky diodes when one is going for maximum volume. They have rather low reverse breakdown voltages so, when a large RF is being detected, a lot of extra

2.) Loose coupling between the detector and ATU (12" separation).

The last plot again shows how the ac "audio" voltage Va and the dc benny voltage Vb vary as different diodes are used in the radio.



The benny voltage (RED DOTS) seems to peak in the vicinity of the benny resistance as before. However, the peak ac "audio" voltage Va range (BLUE CIRCLES), may be shifting toward higher diode rc values than for the tight coupling case.

My assumption is that the detector tanks' parallel resistance at

---

Summary of measurements on some diodes:

The following charts show typical values for Is and n for diodes that might be used in crystal radio sets. One can see, for any particular diode, that Is and n do not vary by much over a moderate current range. Therefore, they may be considered to be dynamically constant when receiving a signal. Each value of n and Is is calculated from two voltage/current pairs as described above. The diode current (Id) given for each of the n, Is pairs is the geometric mean of the two currents used in the measurement. A Fluke model '89 IV' 4-1/2 digit DVM was used to enable measurements down to as low as 15 nA on some diodes. Noise problems cause some measurement error at low currents. That is the reason for the fluctuations in some of the readings. Values of n very close to 1.0 or below are obvious measurement errors. Those low values for n should have come out somewhat higher and the associated values of Is, also higher.

Note that the germanium diodes show an unexpected tendency to increased values for Is and n at the higher currents. The 1N4148 silicon p-n junction shows the expected increase of Is and n at lower currents. The Schottky diodes seem to have pretty constant values of Is and n across the current ranges measured. Experiments described in Article #27 indicate that the measured values of Is and n for silicon Schottky diodes tested here, when used as detectors, remain at the measured values at rectified currents so low that a voice signal is barely readable. This is not necessarily true for all germanium diodes.

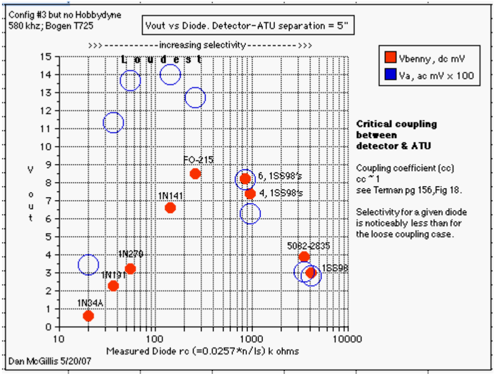
* This Infineon diode has an unusually high series resistance of 130 ohms. The voltage drop across this resistance is low enough in all the measurements to be ignored, except for the highest current one. There, a correction for the voltage drop was made.

Table 2 - Measured n and Is values for various diodes, over a range of currents (Id), in nA.



If Va is in fact related to audio power, then the plot indicates that for this radio, the audio power delivered peaks for diodes with critical resistances in the range of say 50k to 200k - a pretty broad range. The dc benny voltage Vb (RED DOTS) however, seems to peak in the vicinity of about 500k - the value of the benny resistance. As others have noted, the selectivity - as judged by listening - continuously improves as diodes with larger and larger rc values are used. By choosing different diodes, you can tradeoff loudness for selectivity. The plot shows the magic of impedance matching. (Thank you Ben Tongue for your articles!) All this is old hat to some folks but for a novice like me, it's neat to see.

The modulation on my talk show test signal seems fairly constant - as long as measurements are avoided during commercials or the occasional music. A spotting radio helps in avoiding high modulation surprises. The ac signal does still bounce around a bit. Taking 20 random voltage readings per data point and averaging helps smooth the results.

The radio used as a test bed is double tuned with 165/46 litz coils close-wound directly on Amidon 0.5”x4” ferrite 61 rods. The coupling between the detector’s tank circuit and the ATU tank is varied by changing the end-to-end separation between the ferrite rods.

1.) Tight (approximately critical) coupling between the detector and ATU.

The first plot shows how the “audio” ac voltage Va (BLUE CIRCLES) varies as the detector diode is changed - with a small 5” separation between the detector and ATU rods.

A rare germanium diode that seems to be ideal for many crystal radio set designs is the FO 215, branded ITT. A search of the Internet has not turned up a manufacturer's datasheet. ITT is not in the germanium diode business anymore, but from the Internet search it appears that the original company was a German company named ITT Intermetall. Some of their semiconductor business became ITT Semiconductors. This was later sold, around 1997 to General Semiconductor Industries. That business was later sold to Vishay. One source indicated that General Instruments was also one of the intermediate owners. Averages of measurements on three samples of the FO 215 are: Is=109 nA and n=1.02. These measurements were made at an average current of about 250 nA. Interesting note: The average Is of the FO 215 diodes is about equal to the geometric mean of that of the Agilent 5082-2835 and a typical 1N34A. I obtained my FO 215 diodes from Mike Peebles at: http://www.peeblesoriginals.com/ .

Article #27 shows detector measurements of how diodes having different values of Is and n perform as weak signal detectors when impedance matched at both input and out put.

The ac voltage (Va) across the 5.6k resistor load is assumed to be proportional to audio power (=V^2/R). The DVM used is supposed to have a 10 meg input on the “ac mV” scale. It’s specs say it has a 40 - 400 hz ac response, and an rms output calibrated to a sine wave. Since the audio voltage across the 5.6k is not a sine wave, and has frequency components outside the 40 - 400 hz response range, I can only hope that the DVM’s output will be a relative measure of audio power. The DVM is all I’ve got, so it will have to do.

Audio and Benny Voltage Measurement:

May 21, 2007

A lot of the fun playing with crystal radio for me involves "measuring stuff". The "benny voltage" - the dc voltage across the benny resistor in the matching transformer circuit - is a favorite parameter of mine. It's easy to measure with a DVM and it seems to vary with everything. And it's a very good tuning aid.

However, Dave Schmarder has gently and patiently reminded me on many occasions that it's the audio power delivered to the headphones that's important -- that I should try to measure relative audio power as well as benny voltage when evaluating radio changes. The following is my first attempt. Dave thought it might be of interest to the group.

With a DVM as the only measurement tool, and weak daytime talk stations (non sports) as signal sources, my measurements are low-tech. The circuit used to measure the ac voltage (Va) - that I hope is related to relative audio power - is shown in the attached layout.

Diode Modeling Update

Kevin Smith

http://www.lessmiths.com/~kjsmith/crystal/dmodel.shtml

The following explains my first attempt to compare a measured diode characteristics with calculated plots based on the Shockley Equation.

I have been taking serious look into diode modeling and measurement recently in an attempt to better understand these solid-state successors to the humble crystal and cat's whisker detector. There is much good information on diodes to be found in many excellent web sites of course, but there is nothing quite like actually making the measurements and working with them to get a good feel. This page reports some of my protocols and test setups which I have found to be useful.

Most probably the single best web article for the measurement of diode Is and n parameters is given by Ben Tongue in his Article 16. In this article he describes an interesting circuit for the measurement as well as protocols for making them. For my purposes I did not wish to make this a construction project and felt I might get along with good quality meters and my already-built "Diode Test Jig". Essentially Ben Tongue's method consists of making two precision measurements of Voltage and Current through a diode at small signal levels, essentially about 3 and 6 times Is (sufficiently low that the voltage drop across the series resistance Ro can be ignored). The measurements are then substituted into the Shockley equation Is*{exp[(qe/(n*k*T))*(V-I*Rs)]-1} and solved simultaneously for the two data pairs. Mike Tuggle has provided a nice excel spreadsheet to do the math. This spreadsheet, Cal_n_Is.xls forms the basis of my technique and

I am thus indebted to both Ben Tongue and Mike Tuggle for making this project feasible.

In addition to simply calculating the main parameters Is and n, I also wished to measure enough points to plot a characteristic curve, and to compare the measured curve with one calculated directly from the Shockley equation. My first spreadsheet then combined Tongue/Tuggle calculation protocol and a graphical view of the match between measured and theoretical. I did make a few methodology modifications which I thought/hoped would allow added accuracy:

1) Using the full Shockly equation without simplifying for an assumed 25dC room temperature. While the 25dC assumption is generally good and probably within the measurement error (or perhaps not), including the actual measured temperature eliminates doubts of inaccuracies due to this parameter. With the power of PC's and spreadsheets there is no reason simplify the equation.

2) Used Vd = 0.04 and 0.05 V (adequately close to Ben Tongue's recommended 0.039 and 0.055 V) whenever possible. Note for some diodes with significantly different forward voltage drops, Si diodes in partictular I had to use higher values for Vd.

3) Reporting: I decided that, as there is no unique solution to n and Is, each is dependant on the valuse Vd and Id, I feel that reporting both Vd and Id is necessary for repeatability. Naturally I also include the ambient temperature in the report as well, and

4) I included a calculation for Ro (or Rg if you are using Tongue's reference) as that is the goal of the exercise.
A screen shot shown below:

Effect of Diode Rd on Audio Power

http://theradioboard.com/rb/viewtopic.php?t=330
By Dan McGillis

Introduction:
Sep 13, 2011

Kevin - thanks for posting your work. Really good stuff.
Mike Tuggle & Mike Peebles gave excellent advice on choosing a diode.

Here's a plot of how the choice of diodes - and their associated Rd's - affected the relative loudness of one of my crystal sets.
http://theradioboard.com/rb/viewtopic.php?t=330

As you can see, there is a "best" choice of Rd for this particular set if maximum loudness is the goal. Using diodes with Rd's larger than that needed for maximum loudness gave the crystal set more selectivity (and less loudness).

I should note that you get this kind of curve of loudness vs diode Rd when detecting WEAK signals. For very strong signals, all my diodes gave about the same measured loudness. ie. The choice of diode (& it's Rd) doesn't matter too much for very strong signals.

As a side note, my measured Rd's for a given diode are a bit higher than yours and Mike's because I tend to measure at higher Vd's for convenience. And my measurements are no where near as accurate as yours.

Sure is fun stuff isn't it. 😃

73, Dan

then: $d2I / dV2 = d/dV [U-1] = -1 * U-2 * dU / dV$, where

$dU / dV = (dU / dV) + (dU / dI) * (dI / dV)$, and where

$(dU / dV) = (-1 / Is) * \exp [-q (V - I Rs) / nkT]$

$(dU / dI) = (Rs / Is) * \exp [-q (V - I Rs) / nkT]$

Sze's Gamma:

$\gamma = (d2I / dV2) / (dI / dV)$

To use the sheet one need only adjust the voltage Vd to that shown in the first column and record the current Id. If only Vd1/Vd2 and Id1/Id2 are measured then the next step is to adjust the value for "n" until the match between the two equations is exact. I even provided a simple ratio calculation to easily test for a match.

While the math is good and results excellent, I quickly found a couple deficiencies in my method,

1) measurements require high precision and its nearly impossible to land EXACTLY at the voltage required. I needed only to get quite close, let the meters stabilize for 2 - 5 minutes, and then record BOTH Vd and Id.

2) the work is rather tedious and, for a large number of diodes it pays dividends to measure only the needed Vd and Id and let the plot aside. My second spreadsheet thus dispenses with the plot. It is with my second spreadsheet that all my data tables and results are posted.

3) better comparisons between diodes can be made if one targets specific Currents rather than Voltages, discussion on this below.

A view of my current data reporting spreadsheet showing ALL input parameters as well as determined values of n, Is, and Rd.
Data input fields in blue: (target Id1 close to 1.0 uA and Id2 close to 0.5 uA).
Calculated fields in red and black.
Adjustment field "n" in green: (adjust value of n until the ratio of the two calculations = exactly 1).

(Note: the engineers in the crowd will have noticed in the above report than I am carrying a degree of precision not justified by the level of accuracy in my measurements. The final results of n, Is, and Rd should be rounded off to not more than three significant figures.)
A copy of my spreadsheet can be downloaded here..

While measuring a good number of diodes, both Germanium, Schottky, Silicon, and even a few LED's, I noted that Tongue's recommended measurements at Vd = 0.039 and 0.055 V resulted in current reports spread out over more than two orders of magnitude. As the determination of Is and n is not unique but a function of Id, I felt uneasy by this method. While most Germanium diodes I have measured have a fairly narrow range of Forward Voltage drops, (Vf), that of Schottky's can range up to a tenth of a volt. This is the factor responsible for the huge range of measured Id values, see the following plot of I/V characteristics for some selected diodes:

Schottky Law with I*Rs Term

Current, I:

$$I = Is \{ \exp [q (V - I *Rs) / nkT] - 1 \} \quad \text{(implicit expression)}$$

Dynamic Conductance, dI / dV:

rearranging, let: $\exp [q (V - I\,Rs) / nkT] - ((I / Is) + 1) = 0 = F(V, I)$

then: $dI / dV = (- dF / dV) / (dF / dI)$

$(- dF / dV) = \exp [q (V - I\,Rs) / nkT] * (q / nkT)$, and

$(dF / dI) = \exp [q (V - I\,Rs) / nkT] * (-q\,Rs / nkT) - 1 / Is$

then,

$$dI / dV = 1 / \{ (nkT / q\,Is) * (\exp [-q (V - I\,Rs) / nkT] + Rs \}$$

Dynamic Resistance, 1 / (dI / dV):

$$Rd = dV / dI = (nkT / q\,Is) * (\exp [-q (V - I\,Rs) / nkT] + Rs$$

Curvature, d2I / dV2 :

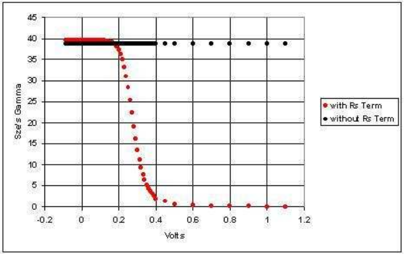
$$d2I / dV2 = d/dV [1 / \{ (nkT / q\,Is) * (\exp [-q (V - I\,Rs) / nkT] + Rs \}]$$

Let: $(nkT / q\,Is) * (\exp [-q (V - I\,Rs) / nkT] + Rs = U$

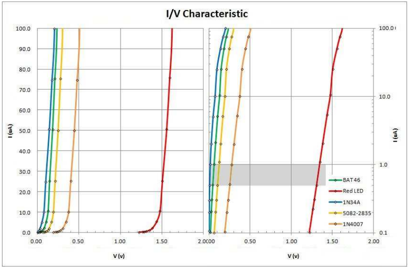
3. With increasing V, the slope (or conductance) itself increases initially, and then levels off at a constant value of 1 / Rs. (red curve)

4. Curvature, the rate-of-change in slope with increasing V, increases initially to a maximum level. After that it decreases and goes to zero as the straight-line portion of the curve is reached. (blue curve)

5. Sze's sensitivity figure, curvature over slope, starts out constant initially but decreases to zero as curvature goes to zero. (red curve in figure below -- compared to the black curve case with no Rs term)



6. Note that Sze's gamma takes a dive near the same voltage where curvature peaks. (??)



In order to get what I feel is a better comparison between diodes, I have decided to target not some pre-determined voltage, but rather target currents of Id = 0.5 and 1.0 uA. On the above plot on the right (with Log Id vs Vd scale) it will be clear that I am aiming at the same part of the characteristic curve regardless of Vf. Hopefully this will allow good comparison between diodes with rather different Vf, even as far as including Silicon and LED's in my mix. On va voir....

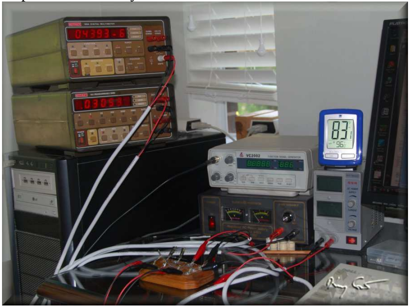
Shockley equation Id = Is*{exp[(qe/(n*k*T))*(V-I*Rs)]-1}
where:
n = ideality factor
Is = Saturation current in Amps
Id = Diode Current in Amps
Vd = Diode Voltage
k = boltzmann = 1.38E-23 J/K
T = temp K = 300
K = dC + 273.15 Kelvin
qe = electron charge = 1.609E-19 cmb

Often simplified to:
Id = Is*(exp(Vd/(0.0256789*n))-1)   [at room temperature]

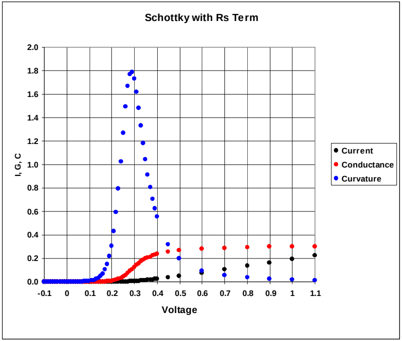
Diode Resistance Rd = VT * n / Is
Where:
T = 300K
VT = k*T/qe = 0.0256789
SO: Rd = k * T / qe * n / Is

I cannot express enough my indebtedness and thanks to Ben Tongue and Ken Khun for their great work and web documentation in matters Diode!

A photo of the current "bench" setup. Keithey 195A pico-ampmeter + Keithley 192 DMM bench meter.



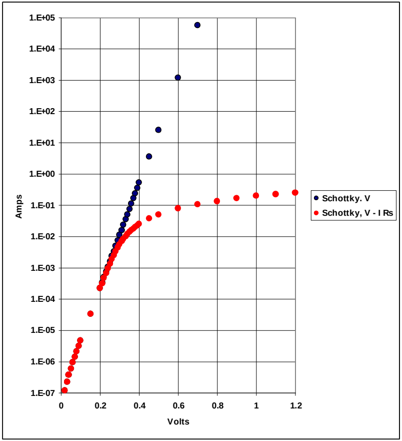
Kevin 09/2011



Diode: Is = 1e-7 A.; eta (n) = 1; Ro = 258 k-ohms; Rs = 3.2 ohms; T = 300 K.

1. At low voltages, current rises exponentially at first but then increases linearly as the I*Rs voltage term dominates. (black curve)

2. Initially resistance (1/slope) decreases exponentially from a high value. Then it becomes constant as barrier resistance R becomes vanishingly small and parasitic resistance Rs becomes the dominant resistance. (resistance curve not shown)



Schottky Behavior with Rs Term

Diode voltage-current behavior is modeled with the Schottky expression that includes the I*Rs term. Below are graphs of some of the resulting quantities.

Effect of Parasitic Resistance Rs on Diode Current

The common Schottky expression predicts extraordinarily high currents for applied voltages above several hundred millivolts (black curve). For example, at the "knee" voltage, 0.7 volts, predicted current is on the order of 50,000 amps! Of course, this doesn't happen. When one includes the effect of series parasitic resistance Rs, replacing V by (V - I Rs), current is tamed to a more reasonable 100 milliamps in this example.

When I*Rs term is included, I appears on both sides of the Schottky expression and cannot be rearranged into a single I term. It must be solved for by trial-and-error. Excel's SOLVER function can be used, but still, each data point must be solved separately.

Diode: Is = 1e-7 A.; eta (n) = 1; Ro = 258 k-ohms; Rs = 3.2 ohms; T = 300 K.

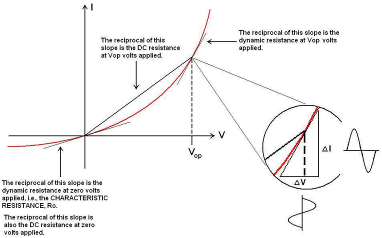
DC RESISTANCE (Shockley-Law):

$$RDC \;=\; V / I \;=\; (nkT / q{*}I) * \ln [(I / Is) + 1] + Rs$$
$$RDC \;=\; R \;+\; Rs$$

Dynamic resistance Rd is the impedance (resistive) offered by the diode to an alternating (RF) signal when the diode is biased by a DC current I. Rd is the inverse of the slope of the DC I versus V curve at voltage point V (or current I). The dynamic resistance at zero volts DC applied is the characteristic resistance. It is the resistance to be considered when matching the diode to, say, the tank circuit in a crystal set. See illustration below.

DYNAMIC RESISTANCE:

$$Rd \;=\; dV/dI = d/dI\, [(nkT /q) * \ln [(I / Is) \;+ 1]+ I * Rs]$$
$$Rd \;=\; (nkT / q{*}I) * \ln [(I / Is) + 1]$$



I
The reciprocal of this slope is the DC resistance at Vop volts applied.
The reciprocal of this slope is the dynamic resistance at Vop volts applied.
V
V_{op}
ΔI
ΔV
The reciprocal of this slope is the dynamic resistance at zero volts applied, i.e., the CHARACTERISTIC RESISTANCE, Ro.
The reciprocal of this slope is also the DC resistance at zero volts applied.

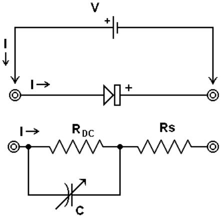
Diode Model

Notes provided to the editor by Mike Tuggle

The diode is modeled as follows:



If a DC voltage V is placed across the diode, current I flows through the diode.

RDC is the non-linear, Shockley-law DC resistance that varies with V and I. RDC is determined by diode-specific parameters Is and eta (n) in the exponential expression.

Rs is the fixed parasitic (bulk) resistance that stays constant with V.

C is the junction capacitance that can be ignored when considering just the direct current (DC) behavior of the diode.

CURRENT:

$$I = Is \{\exp [(V - I*Rs) / (nkT)] - 1 \}$$

VOLTAGE:

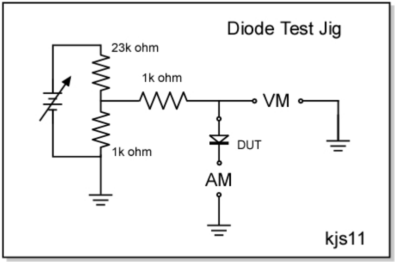
$$V = (nkT / q) * \ln [(I / Is) + 1] + I * Rs$$

Diode Test

Kevin Smith

http://www.lessmiths.com/~kjsmith/crystal/dtest.shtml

So, what is the best diode out there to use? Do crystals always show poor sensitivity compared to germanium? What about Fleming's marvelous device, the vacuum diode? I start by using a test jig, the design shamelessly modified from Dan Petersen in the Nov 2009 Crystal Set Society Newsletter, (if you aren't a member, go sign up to be.. NOW):

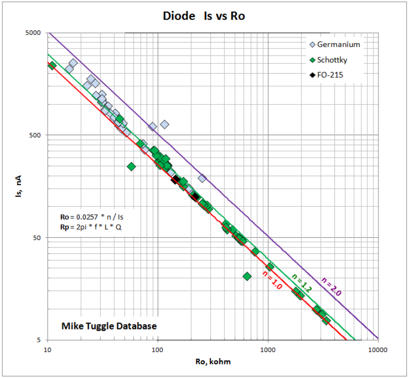


This is a very simple circuit allowing power input, attaching a diode for testing, and sampling both the current and voltage across the diode under test, (DUT). I made a simple modification by adding a voltage divider, about 20:1 at the power input. The power supply can be connected either at the front across the divider, or after the divider in front of the 100k current limiting resistor for higher voltage readings. I get the input voltage from a modest 18V, 2A regulated DC power supply. This unit has both volt and amp controls with digital readouts, nice to use and doesn't take up much room on my desk. Here is a case where I recommend you look at getting a new unit. I looked long and hard on ebay, but found few bargains and few units with the same features. Still, the supply regulator was never designed to adjust the output to precise small values making it somewhat difficult/tedious to adjust. Adding a small rheostat to the test jig may aid for making fine adjustments on the voltage. Another piece of equipment you will need for this test is an amp meter. At first I used a nice small digital meter I found new on ebay for $15 shipping included. It reads amps to a lowest range of 200uA, more than enough precision for the task. For that price get two. Later as I got to making more precision measurements for the determination of diode n and Is I acquired a Keithley 195A bench volt/amp meter with very high input impedance. The DVM is, of course, my trusty Keithley workhorse.

I have received occasional criticism for the simple test jig with the suggestion that proper measurements cannot be taken with the jig as-is. I note that, while the test setup is simple, the instrumentation is high quality and performs the job well. I have had the opportunity to collaborate with Mike Tuggle, comparing our respective measurements. Even my early characteristic curves taken with the small amp meter compare well and provide a good view of the diode and determination of the diode Rs series resistance. The detail n and Is measurements presented here essentially match, though at somewhat less precision, those data from Mike. The reader should have some assurance that the data and measurements found on this page are vetted and reliable.

Easy protocol as follows:

1) Set up the test with the diode and meters clipped to the jig.



I absolutely agree, your data set on diodes is preeminent for its detail and variety of diodes covered. I'll attach a summary index of all the diodes I've measured (ed note: summary chart above). Each diode has a full multipoint analysis and I-V plot, if you're interested in any of those. Quality varies, as the methodology has improved over the years.

Best regards, -Mike-

Hi, Kevin.

Coincidentally, I have been thinking about the measurement of diode I-V's at higher voltage levels. For an 0.4 volt drop across the 1N34A that we've been considering, the Shockley law current through the diode will be some 312 mA.

To measure that with a 50 k-ohm current sense resistor, we would need to supply 15,600.4 volts -- 0.4 volts across the diode; 15,600 volts across the current sense resistor. Obviously not practical, for my setup anyway.

A much smaller current sense resistor is needed. I'd say about 1 ohm. Then there would be 0.4 volts across the diode and 0.312 volts across the current sense resistor -- or 0.712 volts total. That could be done. Whatever current sense resistor is used, its value needs to be known accurately.

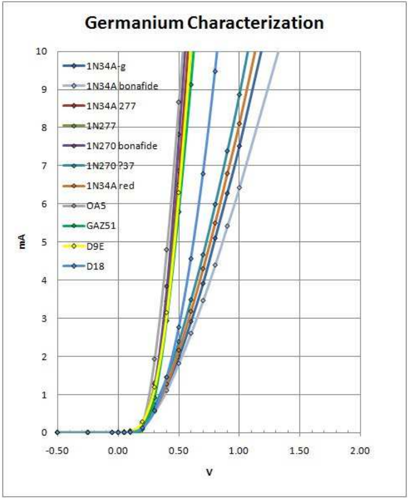
Under these conditions, the DC resistance of the 1N34A is 0.4 volts/0.312 amps = 1.28 ohms. The bulk (parasitic) resistance of the diode would need to be considered. I would suggest multiple measurements regressed by Excel's SOLVER, using the Shockley expression with bulk resistance parameter. Some notes are attached. (p 153).

2) Adjust the power supply until the reading on the DVM meter is where you plan to measure. Adjust the voltage (DVM readout) in steps from 0 to 1.0 Volt in 0.1 V increments and record the current (Amps) in a spreadsheet.
3) Repeat at each tenth volt recording while the spreadsheet makes a sweet graph.

Test Results
First, I offer a quick look at my diode modeling setup. I am currently upping the ante on resolution in order to determine diode parameters Is and n, hoping for success soon! Setup and protocol..

Over a period of a few weeks I ran I-V characterization tests on a good number and variety of diodes, crystals and my two tubes to see how very thing stacks up. The following presents the resulting curves, diode photos, and some puzzling questions/conclusions I churned up in the process. I start off with the realization that when one orders diodes, it is by no means certain what one will get. This seems especially true for the supposedly ubiquitous 1N34A. Unless you see the part number actually on the diode, you probably need to test it to know what it really is. So, lets take a look!

Germanium Diodes



I can get the full 100 mV. With low resistance diodes, the attainable voltage is proportionately less.

My measurement sets typically consist of 20 (10 + and 10 -) V-I measurements. I then regress these measurements against the Shockley equation. (I minimize, using Excel's SOLVER, the sum of squared differences between measured currents and Shockley model currents, by adjusting eta (n) and Is.) Parasitic (bulk) resistance is neglected.

I may be able to get higher currents through a 1N34 by going to a 1.5 volt C cell and shunting across the 5.6 k-ohm voltage divider resistor. I don't want to mess with the 100 k-ohm current sense resistor -- it gets too complicated.

Here's a shot of my test stand:

Test voltage is supplied by a single 1.5 volt AA cell. Design philosophy was to cover voltages (and currents) experienced by diodes in crystal sets. This setup can supply over 100 mV across the diode. The maximum voltage across a diode depends upon the resistance of that diode. With silicon diodes,

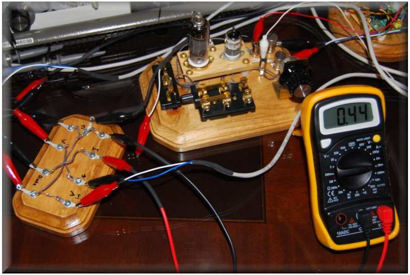
Basic Diode Current Measurement

Diode voltage and current measured sequentially by the same DVM in voltage mode. The 5 meg resistor compensates for the 5 meg DVM input resistance. Here's the complete measurement circuit designed with much help from Ben Tongue:

Photo of the lab with my diode test jig, amp meter, and diode vacuum tubes under test.



Here we see a set of Germanium diodes and photos of the diodes under test. Immediately you should notice two sets of curves, what I call the "1N34A" set and the "1N270-277" set. In this analysis, the second set appears clearly superior in sensitivity and deservedly so. In the photos it is clear that one bunch of diodes I purchased as 1N34A were in fact better 1N277, the black band and thin gold contact wire as well as common curve unite these. "True" 1N34A's have a more robust contact wire. I also purchased a 1N270 and received pretty orange diodes with the number "37" stamped on it, a fairly robust contact wire and a curve that most closely resembles a 1N34A, go figure. Mercifully, I DID manage to get some bona-fide 1N34A's with the part number on the diode, as well as a single bona-fide ITT 1N270 diode with the part number. These are my base for comparison.

In addition to the standard Germanium Diodes tested above, I also have latched my hands on a few "other" germanium diodes for the fun of testing. These include two vintage Russian types, a D9E (in the 270 class) and a D18 (transitional between 270 and 1N34A). Additionally, I got a few FUZZ diodes popular, I suspect, with the guitar gadget crowd. These are larger packages in metal cases so I cannot see how the internal contact is made other that they are stated to be gold bonded point contact type. Clearly these are highly sensitive diodes in my 270 class, the OA5 looking best of the lot. Interestingly, I recently purchased from good Mr. Peebles a few of his "Holy Grail" ITT FO-215 diodes. My measured characteristic for one of these is a dead laydown on the gold-bonded OA5. From the photos, these are in different packaging with the FO-215 in a traditional glass casing. What makes the FO-215 so great is the fact that its resistance Rd is an interesting 150k ohm or so which matches very well with typical moderate Q tank circuits. Interestingly, I find that an old Russian D18 diode has very similar characteristics to the

FO-215 and so much also be placed into the "Holy Grail" class of germanium diode. Take your pick!

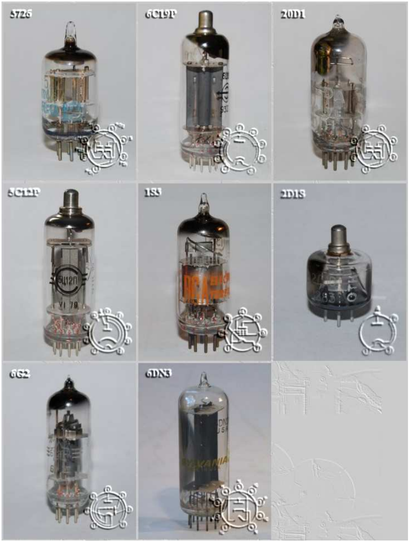
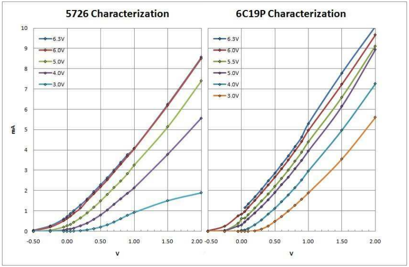
Averages: n = 1.38 Is = 1315 nA Rd = 52 kOhm

The above spreadsheet is based on measurements of the diodes shown above. For the determination of Is and n, I chose at random two examples from my collection of various diodes, (all germanium in this case) and measured via a modified version of the methodology outlined by Ben Tongue and Mike Tuggle. For this work I have chosen to set Id2 about 0.5uA and Id1 about 1.0uA and then read the needed voltage. This is the inverse of the normal method but the justification is that for



Small currents will continue to flow even with a negative bias to the plate, (Contact potential).

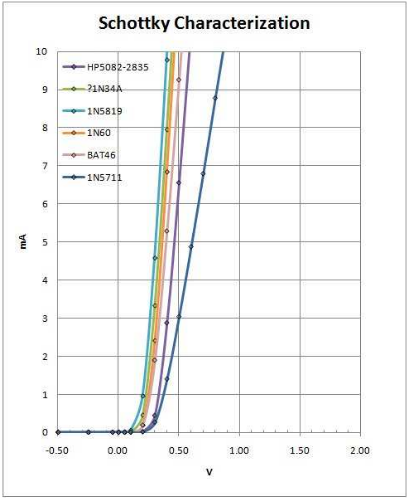
In order to explore this idea, I ran a series of tests with the tubes running at lower operating voltages (effectively diminishing the space charge thus lowering the perveance) as shown:



Here you see the impact of lower operating voltages. With the tube operating between 3 and 4 volts the characteristic curves begin to pass through the origin as in regular solid-state diodes and crystals. It is precisely in this voltage range that I found the radio sensitivity, as measured by loudness to my ear, to be most pronounced. It appears that the diode characteristic needs to pass through the origin of the I-V graph for highest sensitivity. This takes me to the 20D1 tube which operates at 9v but only 200mA. This will still take a power supply to use, but the good thing is that the characteristic curve passes through the origin. Running at its design parameters the tube looks a lot like the 6C19P at 4v.

any diode regardless of forward voltage drop the measurement is made at the same part of the LOG I vs V characteristic. This allows comparison between all diodes. I have included the actual room temperature in the calculations in order to eliminate this variable as a source of doubt or error. All the measured parameters as well as the determined results are presented in order to facilitate repeatability.

Schottky Diodes

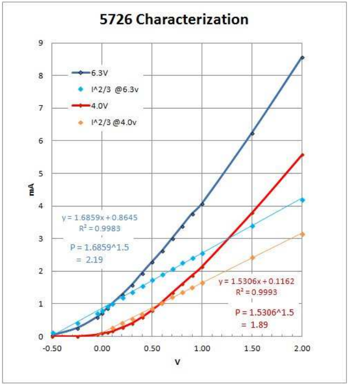


The perveance numbers above range from 0.02 to over 2 mA/V^3/2 (with >2 being good for small-signal detection) and clearly shows my choice of the 6C19P to be an excellent one. I am surprised to see a huge 5.4 for the 6DN3 diode, a color television damping diode. It takes a Novar 9-pin socket and is a large tube so doing more with this tube may have to wait a bit.

Calvert's 2001 published data

Tube	Perveance
6AL5	2.42
6H6	0.50
7Y4	0.58
2X2A	0.017
6V3-A	2.3
6AX4GT	1.42
6AV6	0.085
1A3	0.075

The high-perveance diode tube types I tested show an interesting property in that their characteristic curves do not pass through the origin of the graph. These curves are wholly acceptable as crystal radio detectors although they will require power to operate. What I have noticed with such tubes is that when I turn them off after using them with a radio, on cooling they go through a period of much increased sensitivity (very loud) before fading to nothing. It is as though running them at the full 6.3V lowers their full potential as crystal radio rectifiers. The reason is in the high perveance of the tubes, the anode is already proximate to the space charge before any plate voltage is applied. Effectively, while the plate (anode) "Zero" voltage is measured with respect to ground, the plate itself is still positive with respect to the cathodic space charge.



With my measurements calculating the perveance is practical and quickly done, results as follows:

Tube	Perveance	R2
6C19P	2.54	0.997

BAT46
1N5819

Schottky diodes are very sensitive diodes that work excellently in crystal radios. Their construction and theory are different and I confess to not fully understanding these components. Still, from the characteristic curves, they are excellent! Again, note that you dont always get what you bargain for. Here I found what was supposed to be 1N34A's to be some sort of Schottky of unknown pedigree. The 1N5819, while having the lowest forward voltage drop, has a rather very high Junction Capacitance and will not perform well. Posts on the RaidoBoard Crystal Radio Forum however highly recommend the 1N5711 for crystal sets although the characteristic curve dosnt look that fabulous. Many web pages out there on Shottky diodes, I recommend you do your homework. Of all the schottky's, I note that Ben Tongue recommends most highly the HP5083-2835. The high resistance Rd makes them useful for DX sets with very very high Q tanks. Even so the diodes need to be paralleled with up to 4 or 5 diodes to match correctly the Rd with the tank Rp. I have found these somewhat hard to find and expensive, especially when one requires using several in parallel. I recently measured a few 1SS98 diodes and I discover them to have characteristics extermely similar to the HP and I feel they deserve more attention. Sadly, on ebay they seem to be just as difficult to find and expensive. No free ride!

Spreadsheet below for calculation of Schottky diode n and Is (modified from Mike Tuggle's spreadsheet)

Langmuir-Child Law, the steepness of the I/V characteristic is largely due to the geometry of the tube elements and the volume of electron space-charge between them. JB Calvert's Theory of Vacuum Tubes informs one that this is the property called Perveance in a vacuum diode. Measuring this requires plotting I raised to the 2/3 power against V and taking the slope of the best-fit line through the data. This slope raised to the 3/2 power is the perveance. The following chart illustrates graphically the relation bewtween the tube characteristic and perveance. For the 5726 tube I plot the characteristic in dark blue for the tube heated with the design 6.3 volts. In light blue I have plotted the measurements and raised them to the 2/3 power. One sees immediately that the new curve is linear. The slope of the curve raised to the 3/2 power yields the perveance factor for the tube.

(Note in addition that when running the tube at a more sensitive point with 4 volts only on the heater the perveance is slightly less than spec.).

Vacuum Diodes

When I decided early on to construct a radio based on the vacuum diode (see my Fleming Radio section), I had to find a suitable tube for the project. That began with an extensive search through the datasheets checking vacuum diode properties and reviewing the characteristic curves for a large number of diode tubes. In the above figure I plot the characteristics as best I can on a commpn plot for comparison. I was hoping to find a good candidate with sensitive characteristics and low energy consumption. As you will find, such a beast did not exist. Following this research began a period ot purchase and testing.

I have tested seven different tube types including 6.3V rectifier diodes that take a lot of power to run and are not really suitable for battery use, a 9v dual diode tube (20D1), a pentode/diode tube (1S5) that is designed to run on a battery at 1.5V and 50mA, and a couple miscellaneous but cute tubes. In testing the 1S5, I found the filament never glowed incandescant at 1.5V and, on measuring, was barely sensitive to anything. I cannot imagine this tube would make much of a diode for crystal radio use. I tested different manufacture 1S5 tubes from two different suppliers. No dice. Finally, I tried to push the tube to operate at higher-than-specified voltages. At 4.3V the I-V curve was still very flat, but shifted slightly higher, crossing the Amp axis at about 0.4 mA, (see graph). At 5.5V one of my tubes gave up the ghost and I didnt do more. I pretty much rule the 1S5 out for my crystal radio work. Looks like i'll be needing the power supply when I get around to building/operating that Fleming Radio.

A question remains as to what in fact is different about these tubes to give such different characteristics. While the I/V characteristic of most vacuum diodes pretty much follow the

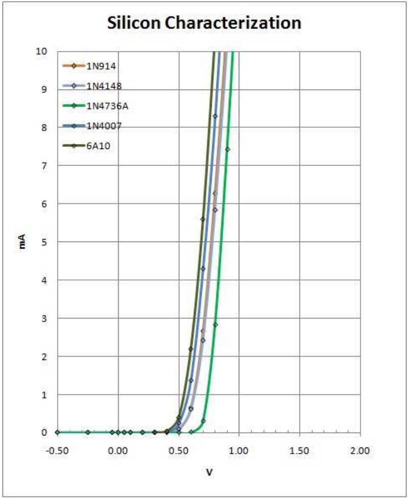
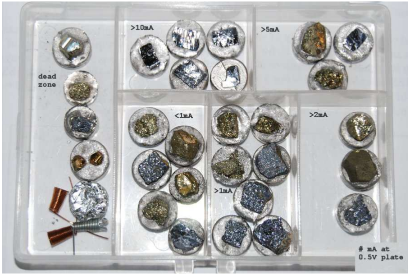
Silicon Diodes

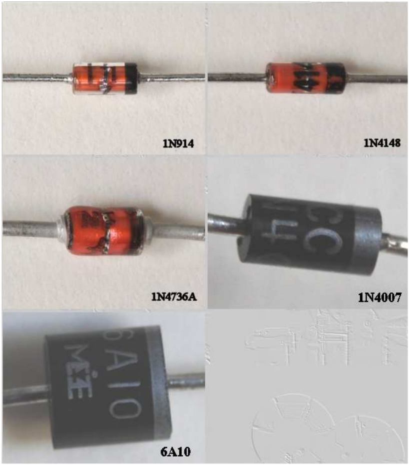




In the photo I indicate groupings based on an easy measure of performance. I note the current in milliamps for each set where the plate voltage is set at 0.5V. The greater the current the better are your chances to get a sensitive crystal, assuming Ohm's Law is not followed! Crystals in the "dead zone" on the left will have their woods metal re-melted for new detector crystals and the bad ones tossed, its tough love for crystals. I find that easily half the potted crystals I make are tossed this way, and only a few can be considered superlative.

Galena" samples (Tintic Utah, or Leadville Colorado) there are numerous hot spots under virtually every place I touch the probe, but in general the sensitivity is good to so so. These crystals are very kind to work with in terms of finding spots and avoiding frustration. Mirror galena on the other hand may have quality hot spots, but any hot spots at all are rare and frustratingly difficult to locate. Here my Philmore detector crystal shines with an almost ideal "Galena" response. To chase down this rabbit I purchased some lovely mirror galena from Sweetwater Missouri. I broke off a few appropriate-size chunks to pot in woods metal and test. At first I was very excited with the high currents I was seeing at moderate voltages. Figured I had struck gold. When these crystals failed miserably to rectify anything in my radios, I re-measured things in both forward and reverse directions. These crystals obey Ohm's law and act like typical resistors, not suitable for radio work at all.

For my pyrite crystals the work has been especially tedious and frustrating. With one of the crystals one "hot spot" alternated, entirely on its own, between hot and bad while I was making the measurements. I would start over and over, sometimes getting interesting readings then suddenly it would drop to low values and I'd start over, back and forth. I present this data as best as I have measured, and I don't intend to go back! You see at least one of the crystals, my "China 1", (from a lead/silver mine in Hunan) gave a sweet classic-looking curve. More to the point, "ideal" curves for natural minerals, are difficult to come by. Most crystals you use will be less than ideal. The good news is that, while listening to your set, poking about for a good spot is far easier than what I have gone through to produce these curves. Your ear will take care of you!



Silicon diodes have good characteristics, but an unacceptably high forward voltage drop making them a very poor choice for crystal radio unless used with bias. The 1N4736A is a Zenner diode.

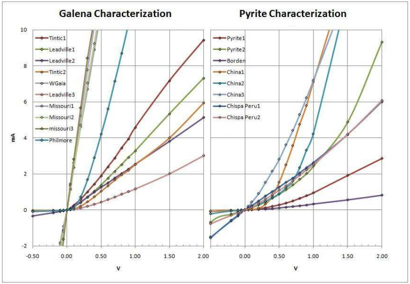
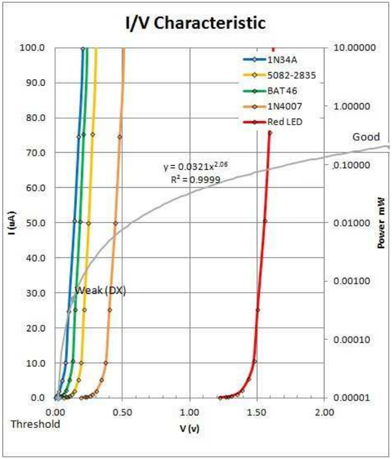
Averages: n = 1.52 Is = 2 nA Rd = 2.4E8 kOhm

The above spreadsheet is based on measurements of the diodes shown above. For the determination of Is and n, I chose at random two examples from my collection of various diodes, (all silicon in this case) and measured with a modified methodology to that outlined by Ben Tongue and Mike Tuggle. In this case, with the radically different forward voltage drop of these diodes from Germanium or Schottky diodes, I have kept the Id values constant (about Id2=0.5uA and Id1=1.0uA) and varied Vd. I have included the actual room temperature in the calculations in order to eliminate this variable as a source of doubt or error. All the measured parameters as well as the determined results are presented in order to facilitate repeatability.



The above curves demonstrate the wide variation in properties and qualities that can be found in natural crystals of galena or pyrite, the two most common and best quality natural stones. In each crystal test I first poked around the crystal for some time to 1) determine a typical sensitivity for the crystal in question and 2) to locate the best hot spot with which to test. This turns out to be a non-trivial exercise on the diode test setup. In a crystal radio one need only listen for the loudest spot. With the test setup one needs test both the forward and reverse current in order to determine if the whisker is on a hot spot or not. Very tedious work! (In retrospect, if I were starting over making a test jig, I would definately add a DPDT switch to readily change between forward and reverse current measurements. I'd probably toss in a rheostat for fine adjustments as well).

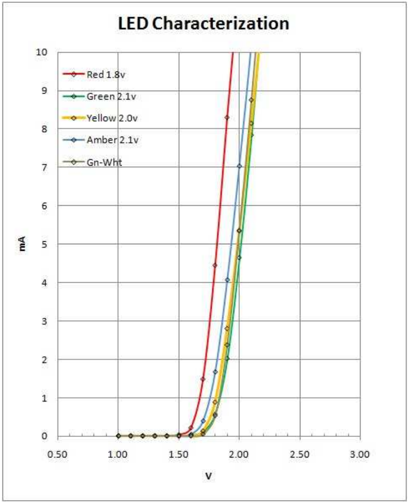
For many crystals there are limited number of possible hot spots, but these may be hot indeed. For most of my "Steel

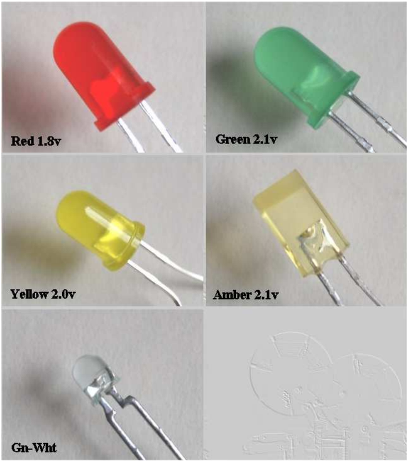


This plot at left takes some actual diode I/V measurements rather than the models presented below and plots them along with the above RF voltage across the LC circuit versus RF power in mW. Here one sees that pushing for very very low Vf (via high Is / low n combinations) pushes the limit of detectable signal power from the antenna. At such minute power levels I imagine the reverse leakage current becomes significant and probably offsets the low operating point gains sought.

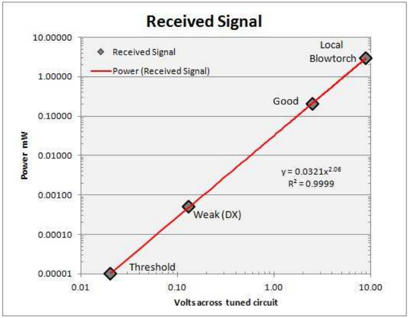
Crystal Galena and Pyrite Diodes

Light Emitting Diodes





As long as I am measuring various and sundry diodes, I figure I ought to include that most ubiquitous of modern diode, the LED. Found everywhere, these diodes are rapidly becoming the low-energy light source of choice for many lighting applications. I have read occasionally of someone asking whether these ought to be useful for radio applications as well. To this question the answer is generally a resounding "No!". The turn-on voltage is waaay above any reasonable value expected to be delivered by an antenna to a crystal set. Still,



The above is an interesting plot taken from the text discussion in "Crystal Set Analysis" by Berthold Bosch. It presents received signal strength across the tuned circuit for various scenarios from threshold audibility to local blowtorch. This plot should be considered a single example specific to his location and antenna/ground system. In the text he describes his antenna an an inverted L 43m long (140') and 10m high (32'), an excellent antenna most of us do not have the real estate to erect, but offsetting this is a poor ground with Rg = 210ohms. Given the offsetting conditions I would imagine this is a good generic example of what received signal voltage and power levels presented across the LC circuit to the diode are likely to be. Bosch cited 40nV as the threshold of audible detectability (impedance matched conditions with 16kohm RF impedance / 4kohm DC phones) and for this plot I pushed it back to 20nV as it gave a superior regression fit.

Additionally I have plotted RF signal Rs as orange circles from published coil unloaded Q (see my section on Coil Q). To convert from Qu to Ql I have made the assumption that loaded Q is about 1/5 unloaded Q for low-end sets while in performance sets it may approach 1/2.5 the unloaded Q. This is only an estimate then, but starting from actual data. To make the conversion to Rs I simply plugged the data into the standard equation R = 2pi*f*L*Q using a scaling factor to divide down Qu to Ql from high Q (1400/2.5) to low Q (100/5). This provides a nice visual display of the expected range for Rs in many crystal sets. I plot the Rs against the value of Ql used. Note that these data are for the case at about 1MHz and inductances between 200 and 300uH, as published.

Matching the diode to the tank is a matter of finding a diode with both sensitive qualities (low n) and an Rd close to the Rs presented to the diode (as per Ben Tongue's suggestions for Peak and Square Law detection). Those diodes with Is's in the 100 - 250 nA (100-280 kohm for n=1.1) or so range have the possibility to match while connected to the top of the tank coil without the use of Q-lowering taps, while untapped matching to high-end high-performance big-Litz baskets will require diodes with Is's in the 35 - 60 nA (500-800 kohm for n=1.1) range. Most "typical" germanium diodes have high Is values (>500, >60kohm) and will require a tap. Diodes such as FO-215, BAT 46, 1N60 and GAZ51 can be matched to many tanks without taps. For tanks with high quality Litz coils one will be using HP 5082-2835 or 1SS98 diodes, generally 3 to 4 in parallel to lower the Rd to the desired range. (Curiously, I have not found any diodes with Rd values in the 300 to 4500 kohm range.) Note that both resistance and impedance are frequency-specific so a match at one frequency will not remain matched across the broadcast band.

this simple answer avoids the actual question, what in fact does the characteristic curve of a LED really look like? Where is the turn-on voltage with respect to the published junction voltage, (assuming you can find that).

To provide just such a look I visited my local electronics store and bought a small handful of LED's, most with the junction voltage listed and took them home to measure. Typical LED junction voltages seem to range from about 1.8v to 2.1v or more. The turn-on voltages look closer to 1.6v-1.7v. Anyone used to working with Carborundum crystals or silicon diodes will be used to biasing their rectifier to get good sensitivity. These LED's once on have a very sharp rise and with a proper bias should work quite well as detector diodes. As a bonus you will get a sweet glow as well. OK, not as cool as the glow of a vacuum diode, but certainly more sensitive!

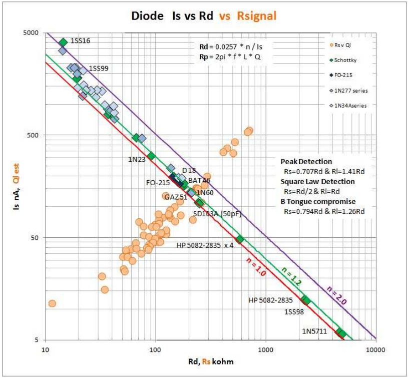
Averages: n = 2.01 Is = Tr nA Rd = 3.8E19 kOhm

The above spreadsheet is based on measurements of the diodes shown above. For the determination of Is and n, I chose at random two examples from my collection of various diodes, (all led's in this case) and measured with a modified methodology to that outlined by Ben Tongue and Mike Tuggle. In this case, with the radically different forward voltage drop of these diodes from Germanium or Schottky diodes, I have kept the Id values constant (about Id2=0.5uA and Id1=1.0uA) and varied Vd. I have included the actual room temperature in the calculations in order to eliminate this variable as a source of doubt or error. All the measured parameters as well as the determined results are presented in order to facilitate repeatability.

Why know the values of Is, n, and Rd of your diodes?

I have been attempting to get a handle on the main diode parameters Is, n, and Rd and how they impact the operation of a crystal radio. My method of choice is to use a graphical approach, plotting charts where variations between plotted parameters become apparent and easy to visualize. I have developed an interesting chart from the measurements above that compares many diodes with respect to Is, n, and Rd, and to understand how this fits into a matching situation with a fuzzy indication of typical tank impedance limits.

Ultimately one seeks a diode with an Rd that matches with and conjugate to the impedance it sees from the tank (+antenna). In the following discussions I will start with the cross-plot of Is to Rd and then proceed to a look at how received RF power plays a part in the selection and why low Is and n are desired.



The plot above shows the relationship between diode Is and Rd. Rd is calculated via the equation Rd = VT * n / Is where VT is the thermal voltage = k * T / q = 0.0257V at room temperature and Is and n are from the measured diodes. k is Boltzmann's constant = 1.38E-23 J/K and q is the electron charge = 1.609E-19 coulombs. On such a plot I can show lines of constant n, and plot the values for individual diodes for which I have spent considerable effort to determine the parameters Is, n and Rd (where Is is the diode saturation current, n is the ideality factor, and Rd is the diode resistance). On the plot it should be evident how changes in n or Is impact a diodes' Rd.

NOTES

INTRODUCTION

The contents of this fourth handbook concerns itself primarily with antenna and grounds as applied to crystal radio (avoiding all the HF world). Finally, It was inspired by my realization that I really didn't understand antenna tuning as well as I thought I did, and especially I didn't understand the Tuggle Circuit. Very little qualitative discussion exists on the web for this in fact. The references I have rounded up here in this handbook should go a long way towards "rectifying" the situation.

In this booklet I start with a good discussion RF field strength, historically, qualitatively and quantitatively. I then bring in some considerations on grounds and especially a discussion of ground resistances regionally and locally as these are essential to modeling my, or any, antenna prior to designing a proper antenna tuner unit. What the follows are excellent resources helping with the design and understanding the functioning of a good "Tuggle Front End". The handbook will help the beginner to quickly get up to speed and allow the experienced builder to find endless new ideas. This is not a book of Hookups or circuit designs, that is covered in my Catalog of Crystal Hookups, nor is it a tutorial on Crystal Radio, that can be found in my Handbook Volume 1.

Finally, although I intend this handbook to consider the antenna / ground as part of the crystal radio system, it is true that antennas receive potentially harmful spherics as well. Due to this, I have included as a last chapter (but not as an afterthought) a section concerning lightening protection.

Much of the material in this handbook is copyright for which I have not sought permission. Therefore this is not presented for publication or copy, and certainly not for profit. It is only my personal resource. I encourage anyone finding this copy to pursue ON THE WEB the web pages identified within. I include the name of the author and web address of each section. I wish to sincerely thank every author presented for their excellent pages and ask forgiveness for my editing into this handbook.

1. "The "Grounds" for Lightning and EMP Protection", by Roger Block, published by PolyPhaser Corporation.

Finally, there should be a large diameter (#4 AWG or larger) copper wire connecting the equipment to the Earth ground. The shorter the wire, the better. Additional information on grounding can be found in Reference 1.

Mains and Power Supply Protection

Just because your radio and antenna are miles away from a lightning strike does not mean that you are protected. Lightning often strikes power lines and produces a large voltage surge or spike that can be transmitted for miles on the main power lines.

Therefore, for maximum protection, all power line interfaces should include a transient voltage surge protector. These devices are becoming quite common and inexpensive. Again, there are simple protectors and those that may include additional protection with built-in line inductors. Just make sure that the surge protector is placed between the power lines and the equipment power supply.

Summary

As stated at the beginning of this paper, lightning damage can be extensive and costly. We have tried to provide you with an overview of things to consider when installing a radio and antenna system but only you can determine how much protection is required. Astron Wireless Technologies, Inc. has access to various lightning protection solutions for most applications. Please call for additional information on lightning protection devices and how they can help protect your investment.

Field Strength Calculations: A History

Radio-Time Traveler
http://radio-timetraveller.blogspot.com/2012/12/field-strength-calculations-history.html
16 December, 2012

A previous three-part series on RADIO-TIMETRAVELLER delved into Field Strength Calculations. It covered ground conductivity's effects on signal strength, measurements quantifying signal intensity, and how to use the FCC Groundwave Conductivity Graphs to calculate expected received signal strength. Mathematical formulas, somewhere, produced those graphs. What is their history? Might we use a simplified formula to calculate expected received signal strength for our DX purposes?

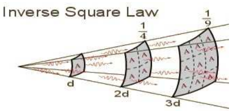
Let's continue with the story behind Field Strength Calculations and explore the 50 year quest for accuracy in calculating signal strength by mathematical formula. It is an interesting tale. We will finish with a handy field strength calculator program I wrote using a simplified formula.

When we talk about field strength, we are really talking about radio propagation - the behavior of radio waves when they are transmitted or propagated from one point on the earth to another, or into various parts of the atmosphere. In our formula quest, we will mostly be concerned with those signals that hug the ground, or "ground wave". It may surprise many who are new to the hobby of mediumwave DXing that daytime ground wave range for a mediumwave signal might extend out to as much as several hundred, and in extreme cases, nearly 1000 miles!

Accurate formulas for calculating expected signal strength at mediumwave and longwave frequencies took many years to develop. Radio originally inhabited the longwaves in its infancy. Many of Marconi's early broadcasts, including his 1905-1906 transatlantic tests, were sub-100 KHz. The trend would be decidedly upward in frequency and downward in wavelength.

At the end of World War I, a fierce battle ensued between the US government and the Department of the Navy over control of the airwaves. The Department of Commerce eventually won and became master of the air and the regulatory agency for commercial radio. They started by establishing two broadcast frequencies: 833 KHz (360 meters) and 619 KHz (485 meters). The Federal Radio Commission took charge in 1926, lasting until 1934 when the current Federal Communications Commission was formed.

Throughout the early years of radio, interest mounted to quantitatively determine the service area of broadcast stations. Engineers redoubled their efforts to derive an accurate attenuation formula. The radio world was focused on accuracy of measurements at broadcast frequencies.



"Accuracy" is the key word here. The Inverse-Square Law, as applied to physics, had been commonly known since Isaac Newton's day in the 1600s. Applied to radio, it stated that the power density of the wave is proportional to the inverse of the square of the distance from a point source. In other words, doubling the distance from a transmitter means that the power density of the radiated wave

range with low VSWR up to about 2 gHz. However, it too must be replaced after a strike although it will not necessarily warn the user by going to a short circuit so preventative maintenance is required.

The quarter wavelength shorting stub is becoming a very popular device, especially above 800 MHz where system bandwidth is generally narrow. It consists of a tuned quarter wavelength shorted coaxial type transmission line that is placed directly across the transmission line. Simple types have a narrow bandwidth, typically 10'-. bandwidth, but are low loss and inexpensive.

The optimum place to locate an input protector is at the entry point to the building where the equipment is located. Don't forget to provide a low impedance ground connection to the protector as described below. Always try to keep the lightning and the protection devices outdoors wherever possible!

Grounding

The most important lightning protection is a good low impedance Earth/ground connection to the associated equipment. The Earth ground connection should be a copper plated rod preferably at least 5-8 feet in length driven into the ground. This ground rod should be located as close to the equipment as possible, typically just outside of a building at the entry point of the antenna feedlines.

Greater protection can be provided by using additional ground rods spaced at least 8 feet from and connected to the original rod. Substituting plumbing, power ground return and other "so called" grounds for a ground rod is definitely not recommended.

will not discharge through the antenna. Furthermore, the boom or mast should be grounded to the mast or tower. More on this shortly. Don't forget to ground guy wires that are used on stabilize towers. They are just as likely to be hit since they extend over a wide area around the tower.

Input Protection

Input protection is typically provided by a lightning or surge protector at the input (or antenna side) of a radio. There are three major types of lightning protection devices for the radio input. They are the spark gap, the gas discharge tube and the quarter-wavelength (1/4) wavelength shorted stub. Each method has its pluses and minuses.

The spark gap is the oldest know lightning protection having probably been invented by Ben Franklin! Basically it consists of two balls or points closely spaced and directly across the transmission line. When a strike occurs, the high voltage present will jump across the points and be conducted to ground. RF transmission devices for 50 Ohm systems such as this have been around since the 1950's.

The shortcoming with this older device is that it may not protect against a weak or lower voltage strike. Adjustment at the factory may produce varying voltage breakdowns. Furthermore, once a strike is taken, the device may fail or short circuit so maintenance is required.

A more recently developed input protection device is the gas tube. It works in a similar manner to the spark gap but can be designed to operate reliably at much lower voltages down to 100 Volts for low power circuits and 250 Volts or higher for higher power applications. Another advantage is device is that it can be designed to operate over a very broadband frequency

at that new location is reduced to one-quarter of its previous value. But did it apply?

"Free-space" formulas calculating signal loss in the vacuum of space or "perfectly conducting earth" using the so-called inverse-square law are indeed accurate for those environments. But the Earth is not a perfect conductor, nor does it represent perfect-world conditions. Free-space formulas alone are not usable for our purposes. You will find many of them on the web, even calculators, purporting to deliver a signal strength solution for a given transmitter-to-receiver distance. They can be ignored as inaccurate. In fact, they are not even close.

Arnold Sommerfeld, 1868-1951

Mathematicians started with a "plane earth" (flat earth) theory when they first envisioned a signal attenuation formula. Brilliant, German-born genius Arnold Sommerfeld, nominated a record 81 times for the Nobel Prize during his lifetime, solved the plane earth general problem by 1909, publishing signal attenuation graphs in 1911. Bruno Rolf, basing his work on Sommerfeld's findings, published more attenuation graphs in 1930, some 21 years later. From this information, the Federal Radio Commission compiled formulas and curves, published in 1931. They were used in hearings and allocation matters at least until 1933. It was just the beginning.

In the intervening years from 1909 to 1930, four more scientists obtained independent solutions of the Sommerfeld problem which agreed with the 1909 solution. That is, except for one difference - an inverted mathematical sign. Apparently none of these authors noticed this discrepancy until the FCC's K.A. Norton, in a letter to the editor of "Nature" in 1935, pointed it out and showed that it was responsible for the anomalies in propagation predicted by the Sommerfeld-Rolf graphs. Norton in 1936 was able to construct a universal curve for prediction of field strength at relatively short distances.

Focusing on the plane earth theory, Sommerfeld expected that the surface or ground wave would be only slightly affected by the curvature of the earth since it is guided around the earth's curve in much the same manner as an electric field can follow around the bend in a wire with a comparatively small loss of energy. This explains the general success of the Sommerfeld plane earth formula at distances far beyond the line of sight. However, two major roadblocks to accuracy still existed.

The first, and most important, was "diffraction". The other, "intermediate distance".

Out beyond what is called the "radio horizon", radio signals undergo atmospheric and ionospheric diffraction, that is, refraction and scattering caused by atmospheric irregularities. This enables AM radio signals in low-noise environments to be received well after the transmitting antenna has dropped below the horizon. It has been shown theoretically that the ground wave attenuation factor at mediumwave frequencies is very little affected by diffraction at distances less than about 55 miles, the approximate "radio horizon" for mediumwave.

DIFFRACTION

---

115 VAC we obtain from a line cord). Let's discuss each of them separately.

Antenna Mounting

It is well known that lightning statistically strikes the highest electrical conductor in an area and then follows the lowest resistance and shortest path to ground. Since antennas are usually mounted in high places, they are very susceptible to lightning strikes. Most antennas have a metallic boom and the elements are often attached directly to the boom so they are a likely target for a lightning strike.

Therefore, the antenna location and how it is mounted is probably the most controversial topic when any discussion of lightning occurs. Ben Franklin gave rise to the theory that the lightning was electricity and found this out when he almost was killed by a lightning strike conducted down the wire holding down his kite. Franklin is sometimes credited with the ball discharger and the pointed rods on houses. As a result, to this day lightning rods with grounding wires are a part of folk law and many are installed on high buildings and homes, especially in areas prone to lightning activity. Properly installed and grounded, these devices surely do work.

Nowadays, new controversy has resulted with the use of spline balls, static dischargers and wicks mounted on antennas and the top of towers. These devices are said to provide a constant discharge thus decreasing the potential for a direct strike. Some users claim a diminished amount of direct hits after installing these devices.

Suffice it is to say, if at all possible, don't mount your antenna on the highest building or tower. Place it a few feet lower and hopefully the fickle lightning bolt, if it generates a direct hit,

The Nature of Lightning

Lightning can form and stay in the upper atmosphere. This is often a beautiful sight to behold as the bolts jump from cloud to cloud. On the other hand, when lightning leaves the clouds and strikes the ground or a tall object, it can inflict instant destruction and even death to those unfortunate to be near the strike.

The energy present in a lightning bolt can be considerable and a direct hit will inflict the maximum damage. It is estimated that a typical bolt may contain a potential of millions (1,000,000's) of volts thus generating currents up to 100,000 amperes! That is very destructive energy. At the same time, the heat in the bolt can have a temperature up to 30,000 K, hot enough to start fires.

A lightning bolt will often drag or jump along the ground. Therefore, there can be considerable damage in a wide area (even hundred's of feet) surrounding the strike. Just ask a dairy farmer what happened to his cows that tried to hide beneath a tree that had a direct lightning strike.

Lightning Protection in General

Lightning protection must be examined from four distinct directions. First off, the place where the antenna is mounted (such as on a tower) is important. Then there must be input protection from the lightning strike itself, typically in the form of a huge and rapid build up of voltage and current at the input to the radio. Thirdly, a proper ground system must be employed to rapidly conduct the lightning bolt energy away from the radio. Finally, protection is required at the output or main power supply such as the line voltage supply (e.g. the

---

Norton, also in 1936, provided curves for greater distances in the diffraction region. These curves, however, were based on an incompletely developed theory. Mathematical solutions were being developed in Europe, and were two years away from completion. Europeans van der Pol and Bremmer published their paper in 1938, offering a more complete solution of the radio diffraction problem for propagation. Never-the-less, the calculation of field strength beyond the radio horizon still proved troublesome, though Norton's remarkable work clarified Sommerfeld's ground wave propagation theory.

The radio horizon at the longer wavelengths, including mediumwave, can be calculated quite simply.

$$\textbf{Radio Horizon} = 8\text{x}10^4/f^{1/3} \text{ (meters)}$$

$$f = \textit{frequency in MHz}$$

For example, the radio horizon for a station transmitting on 600 KHz is about 59 miles.

By 1940 the FCC, through the work of K. A. Norton, had developed a practical method for constructing curves approximately representing the theoretical predictions. The method used the flat earth theory of Sommerfeld out to a distance of about 80 kilometers, and the diffraction theory of van der Pol and Bremmer at relatively great distances, those in excess of 200-300 kilometers depending on frequency and ground constants.

The gap in the curve was still intermediate distances. The Watson transformation, a theory originally described in 1918 by English mathematician G.N. Watson, was an attempt to connect the two. How to incorporate it into the general theory, to calculate the intermediate distances, was still the final problem. In the curves published in 1940, the gap was simply sketched in by a draftsman.

In 1952, George A. Hufford of the National Telecommunications and Information Administration provided a basis for unifying the ground wave prediction methods of Sommerfeld with Watson's diffraction transformation. It had been 43 years since Sommerfeld's 1909 thesis. There was finally light at the end of the tunnel. New curves were added in 1954 for very low conductivity. These were quite accurate, although freehand drawing was still necessary to join the Sommerfeld curve segment to the curve segment calculated for the diffraction field at relatively great distances.

Then in 1958, Hendricus Bremmer, the same Bremmer who in 1938 brought the general solution to the diffraction problem, provided correction terms which completed the search for the practical formula. Engineers could finally calculate ground wave field strength with accuracy. It had been 50 years in the making. The formula was born.

The FCC curves were considered satisfactory for regulatory purposes until it became necessary to convert to metric units toward the end of the 1970s. In a 1979 FCC report, it was recommended that a computer program be written for recalculating the curves using the methods in Bremmer's 1949 book. The program was subsequently used to produce new FCC curves in 1985 which agree within 1 to 2 decibels with the previous curves. However, the 1979 computer program was mathematically deficient in its ability to cover all the range of intermediate distances, and the great distance values it computed were shifted upward to force a match in the middle. FCC curves drawn for the X-band, 1605-1705 KHz, are the most recent. They are the result of precise calculations of field

What You Should Know About Lightning Protection

http://www.astronwireless.com/topic-archives-antenna-lightning-protection.asp

By Joseph H. Reisert

Antenna Lightning Protection

Antenna manufacturers are often asked about lightning and whether their antenna is lightning proof. This is not a simple question to answer. In this application note we will attempt to describe some of the statistical properties of lightning strikes and give some recommendations on how to best protect your installation from damage due to a lightning strike.

It is important to point out at the start that lightning protection is primarily a function of how much time and money you are willing to spend. Obviously, the more expensive the radio and the importance of system connectivity, the more robust your protection should be.

An Introduction to Lightning

Lightning has been around since the beginning of time. In fact, at this very moment, lightning is striking somewhere on the earth. In the lower 48 US states and Canada, lightning is most prevalent in Florida (with an average of 70-100 storm days per year!) and the Rocky Mountains especially in the Colorado area (with an average of 70 storm days per year). In California and the Northern parts of the USA and Canada the likelihood of encountering lightning diminishes to about 10-30 storm days per year. Lightning is most common starting in the spring and ending in the fall with a large peak in the summer but it can occur at any time of the year.

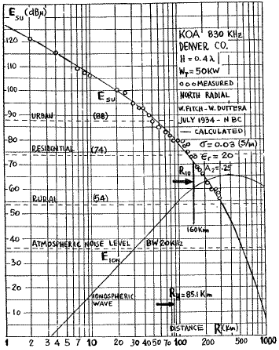
analysis, the author spends some time looking at the accuracy of *low-power SWR testers*. For the Autek RF-1, he reports *good accuracy* for loads from 12.5 to 200 Ohms. He also measures the SWR accuracy of the MFJ-259, and describes it as *very good* across the HF bands.]

Last update: Friday, May 07, 2004 01:40:39 PM

---

strength over the full range of distances of interest, including the previously troublesome intermediate distances.

And thus we have the short version of the history to achieve accuracy in field strength formulas. Stay tuned for the next installment, a program to calculate field strength, based on a simplified formula.



Original measured vs. calculated f/s values for KOA, Denver, 1934 compendium was available. Dan's article, *T-Time for the Analyzers*, is on page 40 of the compendium. Dan has made a number of other contributions in the area of transmission line analysis. Please see his site for more information.

[Epilogue 1 - The ARRL Antenna Compendium #5 has an article entitled: *Measuring Antenna SWR and Impedance*, by Francis Merceret, WB4BBH, on page 148. The author was initially looking into the reliability of SWR measurements. One way to measure SWR is to compute it from the so-called *forward* and *reflected* power. The popular *cross needle* power meter places two meter movements and two indicators in one meter case. One indicates the forward power, and other other the reverse. The intersection of the indicator lines define a point which reveals the SWR, which is indicated on a third scale. I have always found these meters a little difficult to read, and the author indicated that some models do not have high accuracy. Their strong point, in my opinion, is that they can be left in line while transmitting at full power. For purposes such as adjusting an antenna tuner for minimum SWR, these sort of meters are probably very appropriate. I just wouldn't take the SWR value too seriously, especially as it rises. The author also considered an inexpensive noise bridges and one antenna analyzer, the Autek RF-1. His conclusion is: *My results indicate that SWR bridges often do not measure capacitive loads or high SWR values accurately. I found that a noise bridge is more accurate, but that it is also much more difficult to use. The most accurate and easiest instrument to use is a modem, microprocessor-based "RF analyzer"*. When is uses the term *SWR bridges*, he is referring to the power meters that also measure SWR.]

[Epilogue 2 - The ARRL Antenna Compendium #5 has an article entitled: *Baluns in the Real (and Complex) World*, by Frank Witt, AI1H, on page 171. As part of doing some balun measurement discrepancies were due to sloppy measurement techniques.

My Excel spreadsheet data and graphs can be downloaded as Analyzers.xls

Some folks have commented that my results appear to show much more accuracy in these meters than they expected. I think that there are at least two reasons for this. First, it's very easy to introduce errors due to poor measurement technique, primarily excessive lead length. I certainly made several *lousy* measurement runs and had to continue to try to improve the quality of my test fixture. Another reason is that I was measuring what I would call a *shielded system* - a handful of resistors connected to a rather short length of transmission line sitting on my test bench The more common application for an antenna analyzer is to measure, *antennas*. Antennas are designed to pick up signals, and this can include RF from nearby sources. This RF, when presented to the antenna analyzer, can upset the reading. The W8JI calibration page discusses this issue in more detail. A common problem is trying to measure the impedance of a 160 meter vertical when you live a few miles away from an AM broadcast station. I have seen this problem also arise on a 15 meter monoband Yagi. The usual solution is to filter the signal before applying it to the analyzer, keeping the undesired signal out of the analyzer. This must be done carefully, however, since the filter itself can act as an impedance transformer. Some specialized devices exist to filter while not altering the impedance. The MFJ-731 is an example.

ARRL Antenna Compendium #7 has an article by Dan Maguire, AC6LA, which largely duplicates the work on this page. Dan and I worked independently, and we happened to exchange emails after I had finished my page, but before the

Introduction

Radio frequency (RF) can be a complex subject to navigate, but it does not have to be. If you are just getting started with radios or maybe you cannot find that old reference book about antenna aperture, this guide can help. It is intended to provide a basic understanding of RF technology, as well act as a quick reference for those who “know their stuff” but may be looking to brush up on that one niche term that they never quite understood. This document is also a useful reference for Maxim’s products and data sheets, an index to deeper analysis found in our application notes, and a general reference for all things RF.

History (How Do We Know What We Know?)

“If I have seen a little further, it is by standing on the shoulders of Giants.”
–Isaac Newton

The wireless radio technology that is so ubiquitous today is relatively new. However, there is a long and rich background that leads to our modern knowledge. The very first investigations of what we now call the RF spectrum came from early experiments in optics, electricity, and magnetism. The behavior of light was studied as far back as ancient Greece by Plato, Euclid, Ptolemy, and many others, eventually leading to Newton in the late 17th Century. From ancient triboelectric materials and chemical batteries, various theories of electricity were eventually developed by Coulomb, Volta, and Gauss. Likewise, lode stones from ancient China birthed early theories for magnetism from Kuo and Gilbert, eventually propelling the investigations of Ampere and again, Gauss.

Before the early 19th Century, electricity and magnetism were seen as separate forces. However, in 1820 Ørsted found that electric currents exerted a force on magnets, and in 1831 Faraday determined that changes in a magnetic field could induce electrical currents. In 1839, further experiments in electricity led Faraday to show that voltaic electricity (chemical battery), static electricity (triboelectric charge), and magnetically induced currents were all manifestations of the same phenomenon. In 1864, Maxwell combined these discoveries in his paper, "A Dynamical Theory of the Electromagnetic Field,"[2] ushering in our modern understanding of the subject:

Gauss's Law relates electric charge to its electric field: $\nabla \cdot \mathbf{E} = \frac{\rho}{\varepsilon_0}$. The divergence of the electric field is related to the charge density.

Gauss's Law for Magnetism states that magnetic monopoles do not exist: $\nabla \cdot \mathbf{B} = 0$. The divergence of the magnetic field is zero or there is no net magnetic flux entering or leaving a volume.

Faraday's Law of Induction and the Maxwell-Faraday equation state that a changing magnetic field induces an electric field: $\nabla \times \mathbf{E} = -\frac{\partial B}{\partial t}$. The curl of the electric field is related to the change in magnetic flux density.

Ampere's Circuital Law, modified by Maxwell to include displacement current, relates the magnetic field to a current in

This gives me the convenience of the analyzer with a hopefully higher accuracy. I have built several RF networks using this technique, and the results are very accurate.

Conclusion

All of the analyzer plotted results followed the shape of the equivalent computed curve. They are clearly trying to do the job, and in most cases, come darn close. Most of the errors in my data appear in regions of large value swings. This would tend to make the test very sensitive to even slight errors on my part. I tend to consider the regions of the data where the curve is relatively flat over several megahertz. This will reduce the sensitivity to test fixture errors. In most cases, the errors seem to be no more than 5 Ohms. Errors also seem to increase as frequency increases, which could be nothing more than additional testing error.

If I miscalculated the true frequency where the cable was 1/2 wavelength, that would also slightly skew the two curves, creating additional error in the regions of large transitions.

If you use excessive test lead length, you will certainly introduce as much error as any error already in the analyzer. Perhaps the biggest lesson I learned in testing for this page was to keep lead length as short as possible. The next lesson was to use new batteries, or better yet, a beefy power supply with plenty of voltage and current.

I do hope that the next generation of analyzers will accurately resolve the sign of the reactance, and have increased accuracy around zero Ohms. For my recent applications, that would be very helpful. Frankly, I expected the errors to be much greater than I measured. I suspect that many of my unexplained

All of the analyzers are sensitive to low battery voltage. For consistency sake, use an external power supply, or fresh batteries. The MFJ-269 and CIA-HF units have a high current draw, apparently due to the power consumed by the low distortion oscillator. Batteries seem to last substantially longer in the RF-1.

I measured the current drain on the MFJ-269 and the CIA-HF at approximately 225 mA. When the MFJ-269 is placed in UHF mode, the current draw does increase by another 150 mA. If you are going to power one of these analyzers from a *wall wart*, be sure that you have at least a 500 mA supply. Make sure that the external power supply has very low ripple and noise.

Improving Measurement Accuracy

The only technique that I have developed that improves accuracy is in the area of component measurement. I use a more accurate RF bridge to measure a given capacitor and inductor with the highest accuracy that I have available to me. This is a slow process due to the operation of the bridge, and the need for additional compensation computations.

Once I have these measurements, I measure the same components with an analyzer, and determine a simple scaling factor between the two units. I do this for a single amateur band. I then work exclusively with the analyzer, measuring inductors and capacitors with the use of the scaling factors. I move the test leads from the analyzer to the bridge before I make its measurements so that any lead inductance is folded into the scaling factor.

---

a wire: $\acute{\nabla} \times B = \mu_0\left(\acute{J} + \varepsilon_0 \frac{\partial E}{\partial t}\right)$. The curl of the magnetic flux density is related to the current density and the change in the electric field.

These four concepts formed the basis of electrodynamics or modern-day electromagnetic (EM) theory, and are referred to as Maxwell’s Equations. Maxwell had unified the theories of electricity, magnetism, and optics and started the first ventures into electromagnetic-based communication.

The late 19th and early 20th Centuries saw the birth of the electrical and electromagnetic era. Continuing from Maxwell’s work, Hertz, Tesla, and Marconi contributed to EM theory and early forms of practical instruments of communication. In 1887, Hertz showed that an EM wave could travel distances with a basic spark-gap transmitter and spark-gap receivers, and later linked the velocity of those waves to the speed of light. In 1891, Tesla demonstrated wireless power transmission, demonstrated wireless telegraphy in 1893, and filed for the first U.S. patent for a radio in 1897. Likewise, in 1901 and 1902 Marconi began demonstrating trans-Atlantic communication with the first example reaching from England to Newfoundland (nearly 3500km), using a kite-flown antenna.

Just as the theories behind EM communication progressed quickly, radios have also developed at an astounding rate. Wireless telegraphs first appeared in the early 1900s, and developed into the AM radio broadcasts of the 1920s. FM broadcast radio picked up with commercial backing in the 1940s. Satellite communication was quickly adopted after the launch of Sputnik in 1957. With the launch of the Telstar and others in the early ’60s, the use of satellites for relay communication progressed quickly. Through the late ’60 and ’70s, satellites took on larger loads of long-distance communication until submarine cables rebounded with the use of fiber optics in the ’80s. Modern satellites still bear a great burden of media transmission, especially after the emergence of direct broadcast satellite services for television and other broadband media. Ground-based RF communication also progressed from simple numeric pagers in the 1980s, to cellular phones, and eventually the establishment of the ISM bands in 1985 led to our now ubiquitous use of Wi-Fi. These names and technologies mentioned above should be very familiar—these are the giants upon which we stand today.

What Is RF?

RF signals are a form of electromagnetic wave, such as visible light, which make up a portion of the electromagnetic (EM) spectrum. The EM spectrum encompasses all forms of light, which ranges from audible frequencies such as the ubiquitous 60Hz, through the standard radio bands which include AM Radio, FM Radio, TV channels, and other RF bands. The spectrum continues through infrared, visible, and ultra-violet light, to higher forms of EM energy like X-rays, Gama-rays, and cosmic rays.

What we refer to as the Radio or RF spectrum is between the low-frequency waves that we could hear if the EM waves were turned into air pressure waves (20Hz to 20kHz) and the high-frequency EM waves that produce infrared and visible light (1mm to 750nm for IR and 750nm to 390nm for visible (or about 400THz to 770THz)).

Figure 1. Radio frequency spectrum[5]

CIA-HF will not even report capacitance or inductance if the phase angle is -90 or 90. You must use special test leads. The other analyzers do not specify any special test leads.

Pure Capacitive Reactance Test at 3.8 MHz (pf)			
pf	MFJ-269	CIA-HF	RF-1
143	148	157	147
215	220	232	220
430	449	472	438
860	921	972	918
1290	1396	1500	1432

All measurements were made at 3.8 MHz.

The CIA-HF is *picky* about making capacitance and inductance measurements. The impedance angle must be within a certain range that appears to be approximately 70 degrees. I had to increase the resistance of the test leads in order to make the measurements at 143 and 215 pf.

Because of my limited supply of the 430 pf capacitors, and the need to rearrange them in several series/parallel combinations, I had to use about 4 inches of wire to make the connections. I have no doubt that this influenced the readings. The added inductance should lower the capacitive reactance, which increases the pf value. Since the errors all appear to be on the high side, this extra wire may be the issue.

In any case, the accuracy is within 10 percent, and perhaps much better if the lead length influenced the readings. The lead length issue was worse on the CIA-HF because it does not have a ground lug near the UHF connector.

The Effect of Battery Voltage and Current may not know the difference between capacitive and inductive reactance. It knows what to convert to (C or L) based upon the mode you have selected.

Measuring components is also different than general antenna/transmission line impedance measurement because the resistive component is zero, or very nearly zero. All that is being measured is a pure reactance. This is the opposite test to what was performed in the previous section, where pure resistances were measured. It is also the case that typical reactance values may be several hundred Ohms, as opposed to antenna measurements (especially vertical antennas), where resistance and reactance are usually each under 50 Ohms (near resonance).

I again visited the junk box, and found several 430 pf silver-mica capacitors that were labeled as being 1% tolerance. I connected these three parts into several series and parallel combinations in order to create a set of expected values. It is my belief and understanding that these analyzers measure reactance, without directly knowing the type of reactance, and then convert that into units of capacitance of inductance depending upon frequency and the readout (capacitance or inductance) selected by the user. If the reactance accuracy is not a function of the reactance sign, then the accuracy in measuring inductors and capacitors will be the same. In any case, I do not have any *precision inductors*, so I can't make absolute measurements.

The CIA-HF manual suggests that you measure components using test leads that include a 50 Ohm series resistor. In fact, they suggest that the accuracy of the component measurement will be greatest when the phase angle of the impedance is 45 degrees. In the absence of any resistance, the phase angle will be (nearly) -90 or +90 degrees, which is not 45 degrees. The

---

This RF spectrum (shown in Figure 1) is further divided into conventional bands, which are typically classified by their frequency range and broken across decades. For example, the 300MHz to 3GHz range is called the UHF band (designated by the International Telecommunication Union (ITU)). In the UHF, SHF, and EHF bands, organization such as the IEEE and NATO tend to break the bands up into smaller categories.

In the United States, the Federal Communications Commission (FCC) is the governing body that manages the RF spectrum allocation and permissible uses. The role of the FCC and its foreign equivalents is necessary to provide central organization of this limited resource and to establish a framework that allows for compatible operation of the many and varied radio frequency systems. Without these regulating bodies, anyone would be able to broadcast without regard to frequency, power, bandwidth, or duty cycle—overpowering competitive and noncompetitive uses alike. This could result in monopolizing the airwaves and would possibly interfere with essential forms of command, control, and communication. For more information on how ISM radios are governed by FCC and ETSI regulations, refer to application note 1772, “Where to Go for Regulations Concerning Short-Range Devices (SRD)” and application note 3587, “FCC and ETSI Requirements for Short-Range UHF ASK-Modulated Transmitters.”

RF Glossary

Amplitude and Power

V – Voltage: In RF systems, the voltage of a signal is typically referenced to a 50Ω load.

P – Power: In an RF system, power is typically referenced to a 50Ω load.

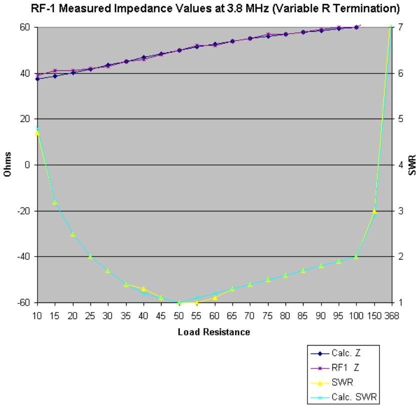
$P = VI = \frac{V^2}{R}$ or in a 50Ω system $P = \frac{V^2}{50}$

dB – Decibels: This is a unitless ratio measure (similar to %) typically used in RF systems when discussing power. The ratio “dBm” is more common in RF applications where the “m” refers to using 1mW as the referenced point. The difference between a 1W reference point (dBW) and 1mW reference point (dBm) is 30dB, that is: dBm = dBW + 30dB. When referring to voltage levels, dB is used to represent a ratio such as an output amplitude to an input amplitude.

$$L(dB) = 10 \cdot log_{10}\left(\frac{V_{Out}}{V_{In}}\right)$$

When used in RF applications, the dB is usually a power ratio based on a voltage gain.

$$G(dB) = 10 \cdot log_{10}\left(\frac{50 \cdot {V_{Out}}^2}{50 \cdot {V_{In}}^2}\right) = 20 \cdot log_{10}\left(\frac{V_{Out}}{V_{In}}\right)$$



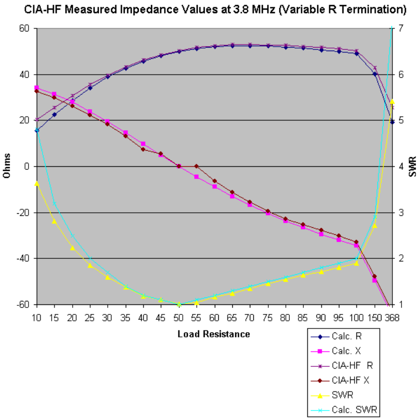
RF-1 Response at 3.8 MHz with a Complex Input

Very good for a tiny little box.

Component Measurements

Another common use of these analyzers is to measure the values of inductors and capacitors. Unlike the typical RLC (resistance, inductance, capacitance) meter, which measures at a fixed frequency, such as 1 MHz, these analyzers will make their measurements at the intended frequency of operation. It is usually the case that the analyzer measures nothing more than reactance, and then converts that into capacitance or inductance using the standard formulas. In fact, the analyzer

Very accurate tracking. Since the frequency is being held at 3.8 MHz, the deviation at higher resistances is not due to frequency. The gap does appear to be real, since the values are rather stable in this region.



CIA-HF Response at 3.8 MHz with a Complex Input

Something a little strange happened around zero reactance again. Otherwise, very close tracking.

Table 2. Power Levels in Different Units

W	dBW $10 \cdot \log_{10}(P)$	dBm $10 \cdot \log_{10}(1000 \cdot P)$	V √50P (w/ 50Ω)
1.000	0	+30	7.071
0.032	-15	+15	1.257
0.020	-16.990	+13.010	1.000
0.010	-20	+10	0.707
0.003	-25	+5	0.397
0.001	-30	0	0.224
316.2µW	-35	-5	0.126
100µW	-40	-10	0.071
0.1nW	-100	-70	70.71µV
0.1pW	-130	-100	2.236µV
10fW	-140	-110	0.707µV
1fW	-150	-120	0.224µV
4.142E-21 (kT at 300K)	-203.8	-173.8	0.455nV

In addition to dBW and dBm, occasional use of other forms of decibels may appear. In all instances, these additional letters indicate what the base unit of reference may be: dBc is carrier referred, dBi is the gain over an isotropic antenna, and dBd is the gain over a dipole antenna.

Field Strength

V/m – Volts per meter: This is a typical measure used for electrical field strength. It is often more common to see values with higher resolution units such as mV/m or µV/m. These measurements are subject to reference antenna gains at the TX and RX portions of the system, the fields are measured at 3m distance (FCC specified7), and are dependent upon the operating frequency (refer to application note 3815, “Radiated Power and Field Strength from UHF ISM Transmitters” for more information).

FCC field strength: for the ISM bands, the FCC defines a maximum field strength based on a linear extrapolation from the defined band end points of 3.750mV/m at 260MHz to 12.5mV/m at 470MHz7, Section 15.231. To calculate this maximum value for frequencies between 260MHz and 470MHz, use the equation:

$$E = \frac{8.75}{210} f - 7.08\overline{3}$$

Where E is the field strength (in mV/m), and f is the frequency of operation (in MHz). For any frequencies above 470MHz and under 900MHz, the FCC caps the Field Strength at 12.5mV/m. In the 902MHz to 928MHz band, the field strength limit is 500mV/m. For unit translation of E(mV/m) to E(dBuV/m) the equation is: $E = 20 \cdot log_{10}(1000 \cdot E)$

EIRP – Effective isotropic radiated power: This is a term that merges the power generated by a transmitter with the efficiency of an antenna into one term $(EIRP = P_T G_T)$. Typically these two items can be broken into the TX power (PT) and the gain of a transmitting antenna, GT(Θ,Φ). However, the antenna gain can be highly dependent on orientation, being a function of Θ (planar angle) and Φ (elevation angle) as noted. To remove these dependencies, the antenna gain can be simplified to a gain relative to an isotropic radiator, which by definition is uniform for any orientation.

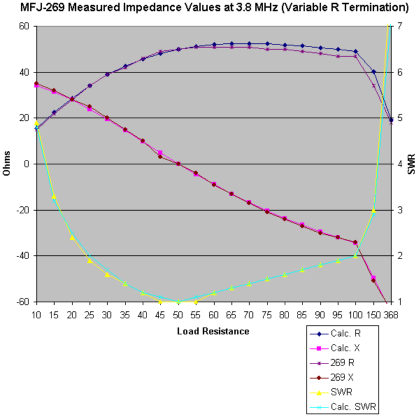
To translate from Field Strength to the EIRP, use the FCC-specified equation:

$$EIRP = 10 \cdot log_{10}(300 E^2)$$

Where EIRP is the effective isotropic radiated power (dBm) and E is the field strength (V/m). This equation assumes the field is calculated at a distance of 3m from the radiated power source.

150	40.22	-49.56	2.9	34	-51	3	42.8	-47.7	2.72	65	3
368	19.16	-64.72	7.2	18	-64	8	25.5	-63.1	5.41	69	7.6

As before, the sign of the reactance was taken from the computed data. For each analyzer I created a graph comparing it to the computed values, for impedance and SWR. The Autek graph, as before, is compared against aggregate impedance, since it does not resolve Z into R and X.



MFJ-269 Response at 3.8 MHz with a Complex Input

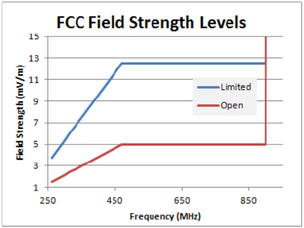
470	12.500	81.9	-13.3
[868]	12.500	81.9	-13.3
902	500	114	+18.8
915	500	114	+18.8
928	500	114	+18.8

Per FCC Part 15.231, average field strength limits G_T = 0dB, and d = 3m.



Per FCC Part 15.231, average field strength limits are restricted based on low-rate periodic operation (limited) or higher-rate periodic and "prohibited" uses (open).

The CIA-HF and RF-1 did a good job of measuring pure resistance, especially at values under 150 Ohms. The MFJ-269 always showed nonzero reactance, except at 50 Ohm of resistance. Practically, most antenna work does not require measuring resistance above 150 Ohms, unless open wire feeders are used.

I checked some of the resistances at other frequencies, up to 30 MHz. All of the analyzers were insensitive to frequency, and produced values nearly identical to their values at 3.8 MHz.

I then used the Lowband software to compute the complex impedance at the input of the cable when the load was set to various resistances. I connected a small noninductive trimmer pot directly to a coax connector, and set it to the different resistance values with the aid of my DMM. For each setting, I recorded the values displayed by each analyzer. Here is the data table. All values are measured in units of Ohms, except SWR, which is dimensionless.

Complex Impedance Test at 3.8 MHz (Ohms)											
Set	Lowband Computed			MFJ-269			CIA-HF			RF-1	
R (Load)	R (Input)	X (Input)	SWR	R	X	SWR	R	X	SWR	Z	SWR
10	15.67	34.19	4.8	15	35	4.9	20.3	32.7	3.63	39	4.7
15	22.63	31.5	3.2	22	32	3.3	25.6	29.9	2.81	41	3.2
20	28.75	28	2.5	28	28	2.4	30.8	26.2	2.24	41	2.5

capacitors. We can continue to use our same piece of coax, but vary the pure resistance at the load, creating a range of complex impedance values at the input (analyzer) side. The same software previously used can be reused to compute the expected impedance values. We won't have arbitrary control over our complex impedance values, but we can at least generate values that we have some confidence in.

In the upcoming tests I'm going to hold the frequency constant at 3.8 MHz. For my current application, I'm most interested in measurements in the 160, 80, and 40 meter bands. 3.8 MHz is a representative value somewhat in the middle of the range from 1.8 MHz to 7.3 MHz.

Perhaps the simplest test is to use the analyzer as an RF resistance meter. In other words, directly connect a pure resistance to the meter and see what value is reported. Using a standard DMM, I measured a set of resistors and then tested them with the analyzers. Here are the results.

Pure Resistance Test at 3.8 MHz (Ohms)			
Resistance	59	CIA-HF	RF-1
17.2 Ohms	16, j 2	15.7, j 0	17
25.4 Ohms	24, j 2	24.7, j 0	25
33.5 Ohms	32, j 4	33.6, j 0	33
50.8 Ohms	49, j 0	50.7, j 0	51
99.8 Ohms	97, j 13	98.8, j 0	99
151.2 Ohms	147, j 21	148.8, j 0	148
385.2 Ohms	358, j 116	380.0, j 0	375
680.0 Ohms	586, j 281	648.5, j 0	660

I happened to have 50 and 25 termination loads. These are completely enclosed termination resistors with an integrated BNC connector. Their actual measured values are shown in the table. The 17.2 Ohms resistor is their parallel combination, using BNC "Tee" connectors.

RF Field Strength

by Kenneth A. Kuhn

Jan, 6, 2008 (draft –more to come)

http://www.kennethkuhn.com/students/crystal_radios/rf_field_strength.pdf

Introduction

The process of building a crystal radio begins with the transmitter. Without the transmitter there would be no point in building the radio.

AM Broadcast stations in the United States operate at 10 kHz intervals between 540 kHz and 1,700 kHz using double sideband amplitude modulation with a modulation bandwidth of 5 kHz (10 kHz total channel width) and a transmitted power ranging from around 1 kW to 50 kW. The broadcast antenna is generally some form of a one-quarter to over one-half wave vertical tower (the entire tower is the antenna) with numerous onequarter wave ground radials. A quarter-wave antenna at 540 kHz would be around 139 meters high!

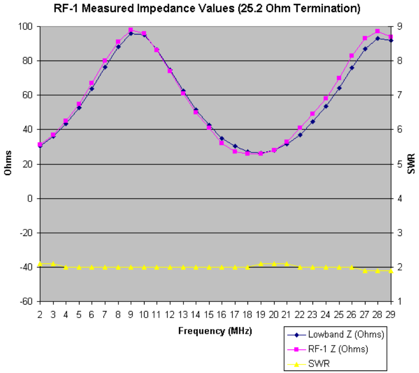
A quarter-wave antenna is attractive because it has a low resistive (i.e. no reactive component) impedance of around 35 ohms. For a 50 kW transmitter the applied voltage to the antenna would be around 1,300 volts rms! This impedance is not the resistance of the tower –that needs to be as low as possible for high efficiency. The impedance of the antenna is the result of the fact that power leaves the antenna as a result of radiated electromagnetic fields –that is the purpose of the antenna.

If the electrical length of the antenna is not a quarter wave then there is a reactive component in the antenna impedance. This reactance is in the way of coupling power to the antenna.

Various tuning schemes can eliminate the net reactance. Antenna designers are interested in maximizing the strength of the electromagnetic field emitted from the antenna. They also have to deal with other limitations such as maximum allowed antenna height, electrical characteristics of the soil around the antenna, and other factors. For these reasons the electrical height of the antenna may deviate from the seemingly ideal one-quarter wave. The result is an antenna that optimizes the broadcast range of the transmitter. Tuning networks can compensate for any antenna reactance.

The signal strength some distance from the transmitting tower is commonly measured in volts per meter. There is a corresponding current measured in amperes per meter obtained by dividing volts per meter by the impedance of free space, 377 ohms. There is no power dissipated in free space as the voltage and current are physically orthogonal. The voltage per meter is a cyclic gradient and is only meaningful over distances that are short (roughly 20 electrical degrees) with respect to a wavelength. Short antenna probes can measure this voltage. Amperes per meter is also a cyclic gradient and is a bit more difficult to visualize as it represents a magnetic field that would exist in response to an actual current. There is no actual current in free space which is an electrical insulator. The magnetic field can be measured using small (with respect to a wavelength) loop antenna probes in which a current is induced.

Thus, electromagnetic radiation is a combination of a cyclic voltage field and an orthogonal cyclic magnetic field. Either alone is just induction as opposed to radiation. As fields spread, the strength of an electromagnetic wave follows a one over distance law. Induction fields follow a one over distance cubed law. Thus, induction fields are useful only for very short distances.



RF-1 Frequency Sweep Data

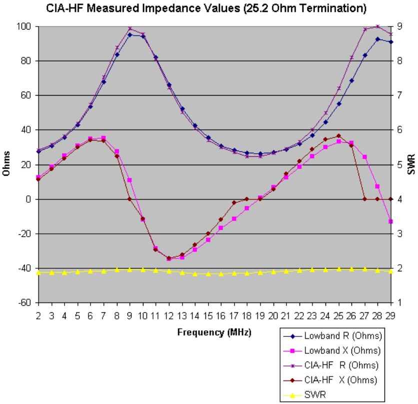
Since the RF-1 only reports impedance (Z), I took the original Lowband data and converted R and X to Z, using the standard formula (Z = SQRT $(R^2 + X^2)$). This derived data is available on the spreadsheet file which can be downloaded at the end of this page.

Impedance at a Constant Frequency

If we want to hold the analyzer at a constant frequency, but yet test its SWR and impedance accuracy, we simply must present it with a range of impedance inputs. We could certainly wire up combinations of resistors and inductors/capacitors, creating reference standards. This approach is complicated by the difficulty of obtaining accurate reference inductors and

CIA-HF

The following graph displays the recorded data when the frequency was swept from 2 through 29 MHz, and the CIA-HF was connected to the test coax with a 25.2 Ohm resistive load.



CIA-HF Frequency Sweep Data

The CIA-HF results are remarkably similar to the MFJ-269 results, although something a little strange seems to happen when the reactance is near zero.

RF-1

The following graph displays the recorded data when the frequency was swept from 2 through 29 MHz, and the RF-1 was connected to the test coax with a 25.2 Ohm resistive load.

In order to engineer a crystal radio we need to know the expected electromagnetic field strengths we intend to receive. Those strengths must be above some minimum or we will hear nothing in our headphones. Data is readily available that gives us a reasonable expectation of the amplitude of a radio wave in terms of volts per meter at a given distance from the broadcast antenna. We must understand not to interpret such data too literally as there are always variables related to terrain and various structures that will affect the data –mostly negatively but sometimes positively.

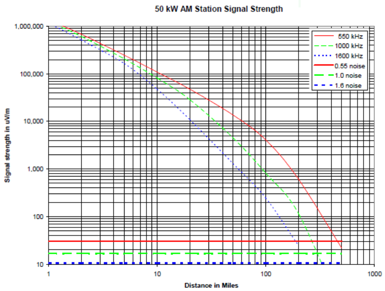


Figure 1: Signal strength with distance adapted from Reference Data for Radio Engineers, Howard W. Sams, Inc. sixth edition, pages 30-3 to 30-5

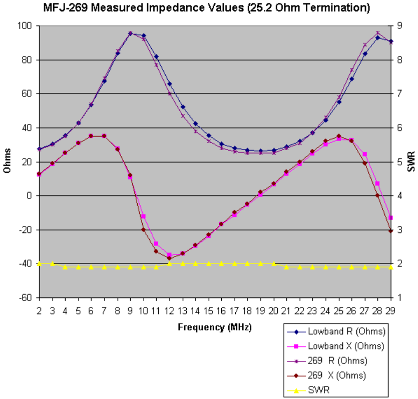
Figure 1 shows typical signal strengths for a 50 kW station during daylight hours. The voltages will be about one-third for a 5 kW transmitter. The increased drop-off with distance is due to the curvature of the earth and varies at night and with weather conditions so a significantly greater range is possible at times. The typical atmospheric noise level for a 10 kHz bandwidth is also shown although this can vary significantly with location and season. Excellent reception is when the signal strength is 100 times the noise level. Poor, but usable, reception is when the signal strength is around 5 times the noise level. The noise floor is only shown for reference. Crystal radios are typically so insensitive that the minimum usable signal is around 1000 times the noise floor.

MFJ-269

The following graph displays the recorded data when the frequency was swept from 2 through 29 MHz, and the MFJ-269 was connected to the test coax with a 25.2 Ohm resistive load.



MFJ-269 Frequency Sweep Data

This graph captures the impedance results, as well as the SWR. This is true for all three analyzers. The SWR trace is shown in yellow, and its values are labeled on the right. Ideally, the SWR would be a nearly horizontal line, at the 2.0 value. The MFJ-269 only displays whole number values.

6	54	35	1.9	55	34	1.91	67	2.0
7	69	35	1.9	70.5	33.6	1.92	80	2.0

29	90	-21	1.9	95.5	0	1.91	94	1.9

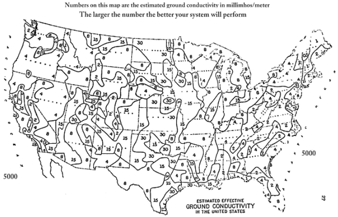
I supplied the reactance sign in the 269 and CIA-HF columns, since the devices do not indicate the sign. I obtained the sign by looking at the computed expected values. The Autek meter only reports the total impedance, not the values of the separate components. The following three subsection graphs compare each analyzer with the computed results from the Lowband software.

Field Strength Calculations

Radio-Time Traveler

PART I: Ground Conductivity

http://radio-timetraveller.blogspot.com/2011/06/field-strength-calculations-ground.html
20 June, 2011

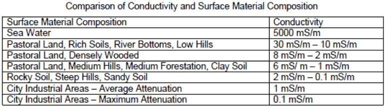


Numbers on this map are the estimated ground conductivity in millimhos/meter
The larger the number the better your system will perform
5000
5000
ESTIMATED EFFECTIVE GROUND CONDUCTIVITY IN THE UNITED STATES

Ground (also called soil) conductivity plays a huge role in how far the mediumwave signal travels during the daytime. Lesser known to many, station frequency is also a factor, and maybe more of one than you would think. Though one can argue successfully that frequency is not a factor in the formula for calculating received signal strength, it indeed becomes relevant as you will see. In this series, let's explore ground conductivity and station frequency and see how they relate to "how far you can hear" on the mediumwave band during the daytime. We will end with a method to calculate approximate field strength for stations of interest.

Many years ago, ground conductivity measurements were compiled into a map titled "Estimated Effective Ground Conductivity in the United States" (Figure M3) by the FCC.

This map is used for the allocations planning for placement of MW stations in the United States. The map presents optimistic ground conductivities and is used when measured conductivity is not available. This information has been used and accepted since it was compiled in 1954.



Comparison of Conductivity and Surface Material Composition

Surface Material Composition	Conductivity
Sea Water	5000 mS/m
Pastoral Land, Rich Soils, River Bottoms, Low Hills	30 mS/m – 10 mS/m
Pastoral Land, Densely Wooded	8 mS/m – 2 mS/m
Pastoral Land, Medium Hills, Medium Forestation, Clay Soil	6 mS/ m – 1 mS/m
Rocky Soil, Steep Hills, Sandy Soil	2 mS/m – 0.1 mS/m
City Industrial Areas – Average Attenuation	1 mS/m
City Industrial Areas – Maximum Attenuation	0.1 mS/m

Soil conductance is measured in siemens per meter but most generally shown in millisiemens per meter. This is the mS/m designation you see in the accompanying chart. The siemens (symbolized S) is the Standard International (SI) unit of electrical conductance. The old term for this unit is the mho (ohm spelled backwards). Conductance (mho) is of course the opposite of resistance (ohm). As you can see, salt sea water provides the best conductance by far (5000 mS/m). The higher the value the better. Average soil runs 6-8 mS/m. Find your location on the map and see what your local conductance value is. Notice also that a distant station's receive path may transition across more than one zone.

Indeed, for all pairs of values in the table, you end up with the same SWR. Here are those equations.

$$|\rho| = \sqrt{\frac{\left((R_a - R_0)^2 + X_a^2\right)}{\left((R_a + R_0)^2 + X_a^2\right)}} \qquad EQ.1$$

$$SWR = \frac{(1 + |\rho|)}{(1 - |\rho|)} \qquad EQ.2$$

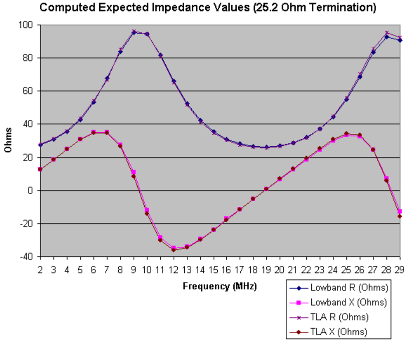
$$|\rho| = \frac{(SWR - 1)}{(SWR + 1)} \qquad EQ.3$$

Equations Relating Load Impedance to SWR

The third equation relates SWR back to the reflection coefficient (ρ). For an SWR of 2, the reflection coefficient is 0.333333... If you grind through EQ.1 with the values from the previous table, you will always end up with an answer very close to 0.333333... By the way, R_a and X_a are the load resistance and reactance. R_0 is the line impedance (50 Ohms). This equation only holds for low loss lines at low frequencies.

Getting back on track, here is the impedance and SWR data recorded from the three analyzers.

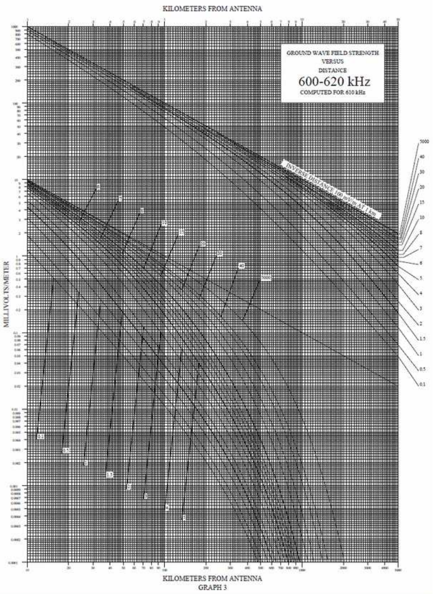
Measured Impedance Values as a Function of Frequency								
	MFJ-269			CIA-HF			RF-1	
Freq. (MHz)	R (Ohms)	X (Ohms)	SWR	R (Ohms)	X (Ohms)	SWR	Z (Ohms)	SWR
2	27	13		28.3	11.1	1.88	31	2.1
3	30	19	2.0	31.7	17.4	1.88	37	2.1
4	35	25	1.9	36.6	23.6	1.87	45	2.0
5	43	31	1.9	43.8	29.8	1.89	55	2.0



Lowband and TLA Computed Input Impedance

As the table and graph shows, the two different methods of calculating impedance diverge, especially at the extremes, but, in general they closely agree. For the purposes of future graphs related to the 2.0 SWR example, I will only compare against the Lowband data.

Here's a little diversion. You might ask yourself: *how can all of these different pairs of R and X values always result in an SWR of 2.0?* I certainly was interested in that question. The answer can be found on pages 24-6 through 24-9 of the ARRL Antenna Book, 18th Edition. Two formulae are needed. The first (EQ.1) takes the load resistance and reactance, and transmission line resistance, and computes the *magnitude of the reflection coefficient.* The second formula (EQ.2) converts the magnitude of the reflection coefficient into the SWR.



FCC Ground Wave Field Strength Versus Distance Graphs

ftp site for finding all field strength vs distance graphs from the fcc:
ftp://ftp.fcc.gov/pub/Bureaus/MB/Databases/AM_groundwave_graphs/

Equally important, the FCC also produces a series of charts known as the "Ground Wave Field Strength Versus Distance" graphs. These 20 graphs in .PDF form are grouped by mediumwave channels in the 540-1700 KHz range, and allow prediction of received signal strength by cross-referencing the distance to the receiving location with the ground conductivity factor between you and the station. These charts cover soil conductivity ranges of 0.1 mS/m to 5000 mS/m. They are still in use today. The only working link I have for them is:

Be sure to get the .PDF versions.

How well a mediumwave transmitter "gets out" is not only dependent on its power, frequency, and the ground conductivity between it and you, but also on the ground condition at its location. The following is a quote from the Standards of Good Engineering Practice Concerning Standard Broadcast Stations (550-1600 kc.), 1939, and is still relevant today:

"The ideal location of a broadcast transmitter is in a low area of marshy or 'crawfishy' soil or area, which is damp the maximum percentage of time and from which a clear view over the entire center of population may be had... The type and condition of the soil or earth immediately around a site is very important. Important, to an equal extent, is the soil or earth between the site and the principal area to be served. Sandy soil is considered the worst type, with glacial deposits and mineral-ore areas next. Alluvial, marshy areas and salt-water bogs have been found to have the least absorption of the signal."

20	26.99	6.62	1.9	26.66	6.88	1.93
21	28.83	12.66	1.9	28.57	13.03	1.93
22	32.02	18.72	1.9	31.88	19.22	1.93
23	37.07	24.64	1.9	37.06	25.30	1.93
24	44.50	29.91	1.9	44.77	30.76	1.92
25	55.03	33.35	1.9	55.78	34.34	1.92
26	68.73	32.59	1.9	70.24	33.47	1.92
27	83.40	24.30	1.9	85.75	24.42	1.92
28	92.87	7.21	1.9	95.38	5.85	1.92
29	90.87	-13.01	1.9	92.31	-15.64	1.92

The Lowband software only reports SWR to tenths. The SWR does slightly drop under 2.0, but the drop is next to nothing, since the line is short, and it is a low-loss cable. As expected, the resistance cycles close to 25 and 100 Ohms, and the reactance varies between +36 (approximately) and -36 Ohms, switching signs when the resistance value reverses direction. Since I sampled at the arbitrary unit of 1 MHz, the actual value extremes are not exactly captured.

I took the resistance and reactance points and graphed them in Excel. Here is that graph.

two programs did not agree exactly, down to the last digit. I suspect that these programs could be made to produce identical results if you understood how to answer the different sets of setup questions with an eye towards how those questions drove the underlying computations, which should be identical, or at least very close.

The expected impedance values, and SWR, are shown in the following table, as a function of frequency.

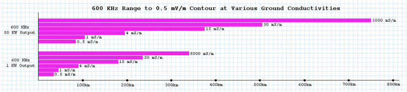
Computed Expected Impedance Values as a Function of Frequency						
	Lowband Software			TLA Software		
Freq. (MHz)	R (Ohms)	X (Ohms)	SWR	R (Ohms)	X (Ohms)	SWR
2	27.61	12.42		27.0	12.42	1.97
3	30.69	18.71	2.0	31.08	18.71	1.97
4	35.56	24.95	2.0	36.07	24.95	1.96
5	42.87	30.72	2.0	43.54	30.69	1.96
6	53.44	34.93	1.9	54.32	34.80	1.96
7	67.69	35.17	1.9	66.83	34.80	1.95
8	83.79	27.65	1.9	85.09	26.76	1.95
9	95.31	10.89	1.9	96.35	8.47	1.95
10	94.43	-12.14	1.9	94.68	-14.13	1.95
11	81.95	-28.45	1.9	81.41	-30.19	1.95
12	66.02	-34.77	1.9	65.12	-35.18	1.94
13	52.40	-33.93	1.9	51.45	-34.67	1.94
14	42.42	-29.55	1.9	41.54	-29.98	1.94
15	35.55	-23.81	1.9	34.79	-24.03	1.94
16	30.64	-17.01	1.9	30.36	-17.75	1.94
17	28.19	-11.51	1.9	27.63	-11.49	1.93
18	26.69	-5.42	1.9	26.21	-5.32	1.93
19	26.31	0.60	1.9	25.91	0.78	1.93

All well and good. Our transmitter is well-located, emitting a good signal traveling over perhaps many kilometers or miles to our receiving location. We either hear it or we don't depending on the natural attenuation decay between us and the transmitter. But just how do we predict the outcome? How do we (abstractly) measure a mediumwave signal's strength at the receiving end? We will use these tools and others to find out.

PART II: Measurements
http://radio-timetraveller.blogspot.com/2011/06/field-strength-calculations.html
23 June, 2011

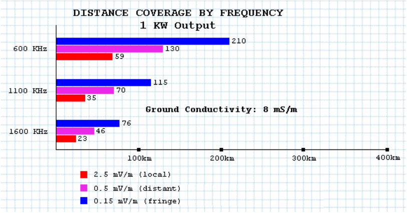
Continuing on with ground conductivity, the higher the conductivity the farther away the station's signal will be copyable. Study the accompanying graph showing the range of a 600 KHz signal at the 50KW power level at various ground conductivities. 50 kilowatts over good ground conductivity of 15 mS/m will produce a very copyable signal at a distance of 375 kilometers (233 miles). At an average to poor ground conductivity of 4 mS/m, coverage is reduced to under 200 kilometers. Excellent ground conductivity of 30 mS/m takes the same signal out to more than 500 kilometers! A purely over-seawater path (5000 mS/m) should result in a fair signal out to about 750 kilometers or some 465 miles.

Also study the graph of the transmitter with only 1KW output at 600 KHz. It gets out quite well considering its output is a mere one-fiftieth of its bigger brother! Its range is perhaps a third of the 50KW transmitter.



Take another look at the M3 map from the previous part in this series. The country is filled with pockets of different ground conductivities, some large in area, some small. The mid-section of the country has some of the best. A large portion of eastern Colorado and western Kansas are in the 15 mS/m range. Most of Kansas proper is an incredible 30 mS/m. Signals propagating eastward out of Colorado travel a long way. Northern Texas and Oklahoma also have great ground conductivity.

Frequency of operation makes an important difference in how far a signal travels. Propagation distance at the high end of the mediumwave band is less than half the distance of that at the low end for the same received signal strength. A study of the two accompanying graphs comparing the distance coverage of 600 KHz, 1100 KHz, and 1600 KHz signals clearly show this.



---

parameters. I also terminated the line with a 50 Ohm load and verified that the SWR was 1.0 across the entire HF range. Any errors within the transmission line itself will throw off all of the results.

For the purposes of this page, I am going to assume that my cable is 180 electrical degrees at 18.90 MHz. This value splits the difference between the three meters. If I need to know the electrical length at some other frequency, I will simply scale this ratio. At 3.8 MHz, for example, the electrical length is:

Length(degrees) = (180 degrees / 18.90 MHz) * 3.8 MHz = 36.19 degrees

The lengths will be used to determine the cable impedance transformation at various frequencies.

I connected the terminated cable to each analyzer, and swept the frequency from 2 to 29 MHz, in steps of 1 MHz. I recorded all of the information that each meter provided, placing the data into a Microsoft Excel spreadsheet. I used an external power supply or new battery with each analyzer.

But first, I used the ON4UN Lowband software (*Lowband*) to compute the expected impedance and SWR at the input of the cable. I used the *lossy* cable model (coax1.exe), which requires the specification of cable loss per 100 feet at two frequencies. For this cable, I specified 0.2 dB at 1 MHz, and 0.6 dB at 10 MHz. That data came from a web site that sells that particular cable. I further used the TLA program obtained from my ARRL Antenna Book back cover to compute the same information. Each program takes a different approach to how loss is entered. I did my best to supply the correct loss data to TLA, but this is based upon looking at typical loss curves, and selecting values. As you might imagine, the results of these and again where the SWR stepped up from 1.0 to 1.1. I used the center frequency of the region where the SWR was 1.0. This region was several hundred kilohertz wide. The values I obtained were:

Half Wavelength Frequency of Test Cable	
Analyzer	Frequency (MHz)
MFJ-269	18.750
RF-1	19.045
CIA-HF	19.150

Because of the lack of agreement, I decided to short the load end of the cable and divide the frequency in two in order to treat the line as a 90 degree section. I obtained the following values.

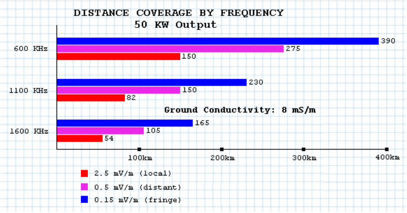
Quarter Wavelength Frequency of Test Cable	
Analyzer	Frequency (MHz) X 2
MFJ-269	18.726
RF-1	19.055
CIA-HF	19.550

It is also possible to compute the half wavelength physical length of the cable using published data. The cable velocity factor was listed as 0.66. The formula is:

f(MHz) = (491.8 / 17.1 feet) X 0.66 VF = 18.98 MHz

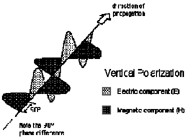
The measured frequency where this cable is a half wavelength was approximately 18.90 MHz. The frequency determined by computation was 18.98 MHz, a frequency error of slightly less than 1/2 percent. The published velocity factor closely agreed with the measured factor. I measured another cable with a 10 percent velocity factor error. To be on the safe side, I would reject lines that showed large deviations from published

---



The common unit used in measuring received field strength is volts per meter, or usually, millivolts per meter "mV/m". This is also the FCC requirement. An odd term, millivolts (thousandths of a volt) per meter. We all know what voltage is, but per meter of what, exactly?

Volts per meter expresses the voltage that would be induced in a one meter long wire placed parallel to the lines of flux of the received signal (remember the electrical flux from a mediumwave tower is vertical, the magnetic horizontal). This induced voltage results from the movement of the flux across the wire.



It is important to note that the E (electrical) component of an electromagnetic field is measured in a single dimension. Why? The intensity-versus-distance relation is a straight inverse rule, not the inverse square law commonly used for calculating received power density. In the perfect environment of space, if you double the distance the signal has to travel, the received voltage (in volts/meter or fraction thereof) is halved. Ten times farther away results in 1/10 of the voltage. This is known as field strength. Power density, a different method of measuring received signal strength, follows the inverse square law. That is, the density is related to the inverse of the square of the distance.

In broadcast parlance, millivolts per meter is often referred to in a different context, that being "dBu", or more accurately, dBµV/m. This is decibels above or below 1 millionth of a volt per meter. It is a convenient way to represent field strength, as the decibel is simply a ratio of values. Be sure not to confuse this dBu (lowercase "u") with the Greek "mu" ("µ") on the new model DSP ultralight radios. They are different. These radios actually measure dBµV - voltage across antenna terminals at a certain impedance, not volts per meter.

The FCC offers a conversion calculator to convert from dBu to mV/m and back.

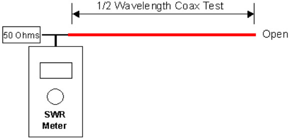
Or, you can figure it yourself by using the following formula:

dBu = 20 * Log(mV/m * 1000)

To reverse the computation, converting dBu back to mV/m:

mV/m = (10 ^ (dBu / 20)) / 1000

But let's put received millivolts per meter into practical application, something a little more understandable. Hatfield & Dawson, Consulting Electrical Engineers out of Seattle, WA have a wealth of interesting mediumwave engineering



Determining Coax Length via the 1/2 Wavelength Method

At some frequency, this length of coax will be an electrical half wavelength. At that frequency, the open circuit at the far end of the cable will be exactly transferred to the input end. This means that the SWR meter measures nothing except the 50 Ohm resistive load, which has an SWR of 1.0. As the frequency is raised or lowered, the open half wavelength will present an impedance in parallel with the 50 Ohm load, and no matter what value that impedance is, it will result in a change in the SWR. After creating this set up, all you have to do is to sweep the frequency of the meter and look for the SWR dip to 1.0. The only caution is to make sure that your frequency is not so high that you are actually measuring a multiple of a half wavelength.

If you wish to consider the cable to be 1/4 wavelength, then you must short circuit the far end. A 90 degree cable reverses the sense of opens and shorts on its two ends. So, a shorted load appears as an open input, which is the same as the 1/2 wavelength case.

Of course I obtained three different readings from the three different meters. The CIA-HF meter actually reports a single lowest SWR frequency. On the other two meters, I recorded the frequency where the SWR stepped from 1.1 down to 1.0, A quick comment on coaxial cable loss. Cable loss does have the effect of reducing the SWR as the loss increases, either due to a longer cable, or higher frequency. We should, therefore, not demand that the SWR stay at 2.0, especially as the frequency rises. The correct SWR value will be less than 2.0. In my tests I will use calculated models of lossy cable in order to understand with the highest accuracy what our expected results should be.

I decided to duplicate the Caron experiment with my meters. I went to the old coax cabinet, and the first similar length I pulled out was 17.1 feet of RG-213 cable. I happened to have a commercial 25 Ohm termination load that measured at 25.2 Ohms with my 3 1/2 digit digital multimeter (DMM).

Before I started the first SWR measurements, I wanted to determine the electrical length of my sample coax at some frequency. Given that information, a new frequency, the load resistance, and cable attenuation, one can compute the actual impedance which should be observed at the input of the cable. If we are willing to believe those results, then we can generate a set of expected values that the analyzers should report.

The published techniques for determining cable length are usually based upon treating the cable as either a quarter wavelength or half wavelength section at some frequency. Once you have either 90 or 180 degrees at some frequency, you can scale the electrical length to the desired frequency. The following test setup is used.

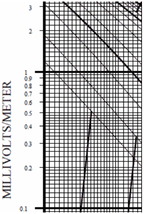
---

documents for perusal, floating about the web. This document seems to describe it best in terms the layman can understand.

From an engineering report by Hatfield & Dawson, 2002:

"MW radio signal strengths are measured in volts per meter (V/m). The FCC requires that MW radio stations provide a predicted 5 mV/m daytime signal and a 5 mV/m nighttime signal or a Nighttime Interference Free (NIF) signal, whichever is greater, over the city of license."

"MW radio receivers vary greatly in sensitivity and much has been written lately about the poor performance of MW receivers built today. The general practice for broadcaster use for coverage is 2 mV/m for coverage in vehicles, 5 mV/m to 25 mV/m for in home and 25 mV/m in downtown office buildings. On a Walkman-type portable radio, you may need as much as 5 millivolts (5 mV/m) of signal to have static-free reception. The reason for these recommended signal levels is to overcome the effects of interference. Sources of interference include fluorescent lights, computers, TVs, office equipment, overhead power lines, and other appliances operating near a radio that can overload the receiver. In a city core, stations generally need more signal than this because of heavy attenuation inside large steel structures like office buildings. In your home, depending on the location, type of radio, and the utilization of any external antennas, you can have good reception with signals between 1 mV/m and 25 mV/m."



radio-locator.com produces widely used antenna pattern plots, available to interested parties over the web. These depict the expected signal coverage of the mediumwave station. radio-locator divides the signal coverage area into three distinct ranges.

1. Local (red line), the area in which the field strength is 2.5 mV/m or greater, where "....you should be able to receive the radio station on almost any radio with moderately good to very good reception".

2. Distant (purple line), the area between 0.5 and 2.5 mV/m, where "....the signal of the radio station may be weak unless you have a good car radio or a good stereo with a good antenna. You may not be able to receive the station at all on Walkmans or other portable radios".

3. Fringe (blue line), the area between 0.15 and 0.5 mV/m, where "....the station's signal will be very weak. You may be able to receive this station if you have a very good radio with a good antenna, but it's possible that interference from other stations may prevent you from picking up these stations at all." This seems to agree with Hatfield and Dawson's report.

Although the analyzers have evolved from that point, measuring SWR is still one of their most important functions.

As I was going through all of my paper and on-line resources, trying to figure out how to make accurate impedance measurements, I came across an article in ARRL Antenna Compendium #3, by Wilfred Caron, entitled: *The Hybrid Junction Admittance Bridge*. In this article, he uses an evaluation and calibration strategy which is based upon a section of coax cable, and a fixed resistor. He connected a 25 Ohm resistor to the end of a 16 foot length of RG-58 coax. What do we know about that circuit? Ignoring transmission line loss for a moment, we know that the SWR measured at the input of the cable should always be 2.0, at any frequency. In addition, the impedance measured at the cable input will change as a function of frequency, displaying both resistive and reactive values. The resistance will vary between 25 and 100 Ohms, and the reactance will swing both positive (inductive) and negative (capacitive) around zero Ohms. When the impedance is exactly the load impedance, 25 + j 0 Ohms, the line will be an electrical half wavelength, or multiple of it, at the target frequency. All of the impedance values will repeat every half wavelength. Peter Dodd, G3LDO, has used this same approach to evaluate his Autek VA-1 analyzer, and his HP4085A vector impedance meter. Those results are presented on one of his web pages.

So, for the price of a resistor and a short length of coax cable, we can present a range of impedance values to an SWR measuring device that should always read 2.0, at any frequency. In fact as we sweep frequency, the impedance values will change, but always representing a 2.0 SWR. This is conceptually similar to drawing the 2.0 SWR circle on a Smith Chart, and moving around on the circle.

While all of these analyzers can be used as RF signal generators, the CIA-HF is, by far, the most stable of the three. In order to use it as a signal generator, you must set the *width* to 0, so that the unit emits a constant signal. Otherwise, it generates RF periodically, as it takes frequency sweep readings and updates the screen. The only issue is that the analyzer then emits a tone which is in proportion to the SWR. This can be a little annoying, but it is not that loud. The quality of the CIA-HF waveform is also dependent upon battery voltage and current. If you do not provide it with sufficient power, the output waveform begins to resemble a square wave, as opposed to a sine wave.

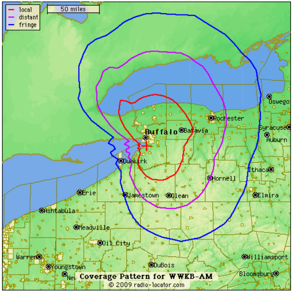
Autek RF-1

The Autek RF-1 is often noted for its very small size. It's easy to carry around, for example, to the top of an antenna tower. This unit is several years old. Unlike the MFJ and AEA units, which measure both resistance (R) and reactance (X), the RF-1 only measures total impedance (Z). Autek sells an updated model, the VA-1, which does report resistance and reactance. Both units are the least expensive of the alternatives.

My software version number is 9.7.

SWR Measurements

The initial use of the portable antenna analyzer was to measure SWR. SWR meters have been around for a long time, but they tended to be meters which we used in the radio shack, excited with transmitter power, often times hundreds of watts. They were not suited for making adjustments out at the antenna. Early antenna analyzers were nothing more than a low power variable oscillator, frequency counter, SWR sensor/bridge, and a detector meter, all placed in a battery-operated package.



Another important factor in our quest to predict received signal strength is transmitter antenna efficiency. Size does matter. The better the antenna, the better the station gets out. Returning again to Hatfield and Dawson, now discussing mediumwave antennas:

"MW antenna heights are referenced to a wavelength (this only includes the radiating portion of the tower). In MW broadcasting, 5/8 wavelength (or 225°) antennas are more efficient than ¼ wave antennas. A ¼ wavelength (or 90°) antenna is near the lower end of acceptable antenna heights. Antenna heights much below ¼ wavelength are undesirable, as efficiencies decrease dramatically below this height. A 225° antenna provides the maximum coverage and is the theoretical maximum. The efficiency decreases for antennas taller than 225°, which results in reduced coverage. In summary, taller towers are more efficient and shorter towers decrease coverage and are more difficult to work with."

So back to our quest of received signal strength prediction. Few documents are available which demonstrate how to predict "real-world" surface propagation distances at mediumwave frequencies. Many analysts use vanilla formulas for calculating free space path loss using the inverse square law, computing the path loss (in dB) from transmitter to receiver. The path loss, in turn, is used to determine the received field strength value.

Unfortunately, free space path loss assumes a perfect environment, like you would find out in space or over a perfectly conducting earth. Be wary of cute little field strength calculators on the web, their resultant field strength figures are almost an order of magnitude higher than what is seen in real life. Formulas exist which will predict field strength at mediumwave frequencies, but the math is well beyond the average person's ability.

A simpler method exists to ballpark the figure we want. We need but one more piece of information to complete the puzzle. That is the millivolt per meter level at one kilometer from the station transmitter, emanating in your direction. Using that with the FCC's Ground Wave Field Strength Versus Distance graphs and the M3 conductivity map we can estimate the received signal level in mV/m to fairly good accuracy at our location for any station.

The next part of this article will show you how to do that. But let me leave you with this before we go. What information can we derive from the FCC graphs and other station data to maximize our daytime DX distance?

1. The lower frequencies propagate better per unit of distance. Stations near the low end of the broadcast band propagate nearly three times farther than ones at the highest end, for the

Shortly after I purchased my CIA-HF, I learned that the phase angle was considered to be *unreliable* under 8 degrees (-8 to +8 degrees) [on more recent units, this unreliable region has been reduced to 4 degrees). For that reason, I tend to think of the analyzer as not reporting the sign of the reactance, but if you are willing to use the Data Screen, and be careful under 8 degrees, the unit does report indeed the sign.

Here is a screen shot showing the resistance, reactance, and SWR of a dipole antenna fed with a tuner, and adjusted for resonance at 14.200 MHz. The data was transferred over a serial line from the CIA-HF to the computer, and displayed with my viewing software.

CIA-HF Data Displayed on a Computer

MFJ does make available a calibration procedure for the 259B (I have never asked about the 269). Tom, W8JI, has also placed a calibration procedure on his web site.

AEA CIA-HF

I have one of the early CIA-HF units, serial number 0341. This unit has an LCD screen which can produce actual graphs of measured data, such as SWR, impedance, resistance, and reactance. In addition, the unit has an RS-232 serial interface, which can be used to interface the analyzer with a computer. Several software packages exist. I use one that I wrote myself. Unlike the other analyzers, the CIA-HF takes a few seconds to update the screen. This makes it less useful for use while *tweaking* a control, since it takes a few seconds to see the updated data (there is a special SWR mode that updates quickly, and produces an audio tone in proportion to the SWR). The CIA-HF had several hardware updates which were added in its first year of production. My unit predates all of those upgrades.

My software version number is 1.4.

On this web page, I claim in several places that these analyzers do not report the sign of the reactance. That is certainly true for the MFJ-269 and the RF-1. The CIA-HF is a more complex story. When you are on what is called the *Data Screen*, the sign of the reactance is indicated by the sign of the impedance angle, ranging from -90 to +90 degrees. A negative value indicates capacitive reactance, and a positive value indicates inductive reactance. As best as I can tell, this is the only indication of the reactance sign. In all other data displays, the reactance or phase angle is always shown as an unsigned number. On the Data Screen, the angle has an explicit + or - sign.

---

same power output and same ground conductivity. The lesson: listen to the lower end of the MW band if you want extreme distance in reception.

2. Look for over-water paths. A local example: Ground conductivity around here in the Rochester, NY area is about 8 or a little less, tending towards the 6 mS/m figure judging from reception experience. Without passive loop assistance, normal daytime reception limits seem to max out at about 150 miles. That is, except for two stations: WJR-760, Detroit, MI and CKLW-800, Windsor, Ontario, Canada, near Detroit. These two are out at about 250 miles or about 400 kilometers. Why are they receivable? Most of their signal path is across water over the east-west length of Lake Erie into Rochester. Reception is routine on most simple radios with medium or better sensitivity.

3. Study station antenna patterns. The FCC web site is great for this. Virtually all stations with multiple towers have directional patterns and the FCC makes the pattern plot available in .PDF form. Study the plot and pay particular attention to your azimuth away from the station. Pick stations that push a lot of signal in your direction. They are the best prospects. Example: WXXI-1370 pattern

4. The radio-locator "fringe" 0.15 mV/m boundary seen on their plots is just that - fringe. Many stations are copyable at this boundary and beyond on a sensitive radio. Don't hesitate to try for them. Example: Denver stations KHOW-630 (only 5KW), KKZN-760 (50KW), and KOA-850 (50KW) all have excellent strength east to well past Hays, Kansas (300+ miles, or 483+ km) despite the fringe zone ending miles back towards the Kansas/Colorado state line.

The jury seems to be out on how far ground conductivity plays a role in daytime propagation. Some documents refer to the 55 kilometer figure, others to 150 kilometers. My bet is it is well beyond the 150 km figure as I have routinely heard stations at the 800 kilometer range during high daylight hours at all times of the year.

PART III: Calculating

Radio-Time Traveler

http://radio-timetraveller.blogspot.com/2011/06/field-strength-measurements-calculating.html

25 June, 2011

As stated in the previous post, one more piece of information is required to complete the puzzle of calculating received field strength. That is the millivolt per meter level at 1 kilometer from the station transmitter, eminating in your direction. Notice I said "eminating in your direction". It is not good enough to simply calculate the mV/m level at 1 kilometer for the station's overall power output. Two things must be accounted for that change that result and would make our field strength calculation inaccurate. They are:

1. Antenna efficiency. A mediumwave tower or array of towers will be more or less efficient depending on their radiation length(s). The FCC provides us with a figure called RMS Theoretical for every station's antenna array whether it be one tower or several, measured in mV/m. Reflected in this figure is the efficiency.

2. Pattern gain. Multiple tower arrays inherently have broadcast patterns. Meaning, of course, they aim to broadcast a majority of their signal in a certain direction to cover their market audience and/or avoid co-channel interference with

Meet the Players

Here are the three antenna analyzers that I owned and tested at the time of the creation of this web page. Please click on the picture for a larger view.

Antenna Analyzers: MFJ-269, RF-1, CIA-HF

The [MFJ-269](MFJ-269) looks like the very popular MFJ-259B. There are some differences. It has a button labeled *UHF* which enables the device to operate up through the 440 MHz band. For my purposes, the primary difference is that the 269 uses a 12-bit A/D (Analog to Digital) converter, which is claimed to produce more accurate results. It is my guess that other analyzers use 8-bit A/D converters, since they are less expensive, and often available directly on the microprocessor IC. The 269 is somewhat more expensive than the 259B.

My software version number is 1.24.

results, they must be used in conjunction with a signal generator and a detector/receiver. Depending upon what you are trying to measure, several computations must be performed to arrive at the result. It can sometimes take *minutes* to make a single measurement with an impedance bridge setup. The delay is due to having to *balance* the bridge, which is a process of adjusting two controls until a very sharp null is found. Another alternative, perhaps the best, is a lab quality impedance analyzer. HP has made a number of models over the years that seem to cost well in excess of $10,000. That takes them way out of my hobby budget. So, for the money, these analyzer boxes are a great value, even with limitations and errors. Overall, their accuracy appears to be quite good.
It's also true that I tested exactly one of each of these meters - the one that I own. Each is several years old, and while I don't believe that I have ever dropped or abused them, they have been well used. I assume that there is one or more *calibration adjustments* for each analyzer, and I have no idea if my units are well-calibrated, or out of calibration.

I don't know how representative my units are of each model, or if there have been design improvements over the years that would change the results.

Finally, the battery quality and lead length will influence results. You can obtain better results if you use fresh batteries (or an external power supply) and short leads. At HF frequencies, even a few inches of wire can act as an inductor with several Ohms of reactance. I can't stress this enough. Short leads, better yet, no leads.

another station. Where you are in relation to that pattern is important. If you are in the major lobe of a 50KW station, it may be pumping upwards of 100KW towards you, or more. If you are in a sharp pattern null, it may only be beaming hundreds of watts towards you. The amount of millivolts per meter "facing you" is the important figure. The FCC provides that as well, in their pattern plots.

There is only one case where we will need to do a simple extra calculation to arrive at the full millivolt per meter level for a station. That is for stations with a single tower only. I will explain why in just a minute.

So let's put together what we need. First, pick a station within reasonable distance you think you'd like to log. Note its frequency. Next, gather the following four things:

1. The ground conductivity in mS/m between you and the station. Use the M3 conductivity map. If the station path crosses a couple of zones, estimate the average ground conductivity for the entire path. The resultant figure should fall between 0.1 mS/m and 30 mS/m, or possibly higher if part of the path is over salt seawater.

2. The Ground Wave Field Strength Versus Distance graph for the frequency of the station, one of the 20 graphs published by the FCC. Several frequencies are usually grouped into one graph. The graphs are in .PDF form. Have your .PDF viewer ready.

3. You will need to find your distance to the station in kilometers, and also the reverse bearing from the station back to you. Many calculators exist on the web which will compute this information. The FCC has a good one, be sure to check out their calculator. These calculators require you to know the

latitude and longitude of both your location and the station's location.

www.wikimapia.org is a great way to determine your home latitude and longitude as it has a crosshair defining the center of the map, and thus the latitude and longitude. Move the map to your exact location and read the latitude-longitude in the web browser's address bar.

The station's latitude and longitude can be found in a couple of ways. The FCC's AM Query web page allows us to query the station by call sign. The search output will display basic information like latitude and longitude. Click on the call sign link and you will be taken to the FCC's web page for the facility (station). Example: WHAM-1180 page.

4. The last item. Get the millivolt per meter value at 1 kilometer from the station transmitter, headed your way. The method of locating this figure will depend on whether the station has one antenna tower or multiple towers in its array.

Determine if the station uses a single tower or multiple towers for the service you are interested in. This information can be found on the FCC's web page for the facility (station), as shown just above.

Note that stations may have more than one entry on the page, one for each service they operate under, i.e., UNLIMITED, DAYTIME, NIGHTTIME, CRITICAL HOURS. Be sure you are looking at the correct service. Sometimes stations use a different number of towers for day and night.

mV/m for multiple towers.

The mV/m figure is gotten from the pattern data. It's simple.

W8WWV - Analyzing Three Antenna Analyzers

Greg Ordy
http://www.seed-solutions.com/gregordy/Amateur%20Radio/Experimentation/EvalAnalyzers.htm

Introduction

On this page I would like to present some measurements that I made with three of the popular antenna analyzers. I became interested in their accuracy when I had an application where I wanted to make accurate measurements of relatively low impedance values. Values where the resistance and reactance were close to zero Ohms, certainly under 50 Ohms. I had no reason to doubt any of the measurements, but from time to time I would make measurements with more than one of the units and find that they might differ by up to 10 Ohms. For many applications this difference is not significant, but I decided to see if I could determine how the analyzers compared to reference values, as opposed to each other.

Accuracy and Value

I'm not trying to present a detailed evaluation of these analyzers, or to rank their quality. My measurements and their accuracy are not precise enough for that purpose. While it's clear that these analyzers can report results with error, they are all a tremendous value, and a useful addition to any amateur radio station.

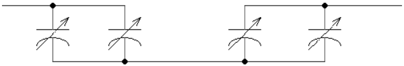
I call them tremendous values because I don't know how to make better measurements without spending substantially more time and/or money. Historically, impedance measurements were made with the *impedance bridge*. While a laboratory quality impedance bridge can produce excellent

Variable Capacitor Wired Wiperless

By Jim, Amateur Radio Station KR1S

http://theradioboard.com/rb/viewtopic.php?t=3262&postdays=0&postorder=asc&start=15

If I'm reading this correctly, a schematic would be:



For a four-section, 500-pF per section cap, the total C would be 500 pF.

Multiple tower arrays will give you the option to display the pattern plot. The pattern plot link will be under a heading that looks like this:

Horizontal Pattern at 1 km radius (Sections 73.150 and 73.152):
    Electric Field Strength pattern plot
    Pattern Data for WXXI

Either link will give us the information we need, though the "Electric Field Strength pattern plot" gives a nice graphic pattern plot for the station. Click one of the links.

RMS Theoretical values, and in some cases RMS Standard or even RMS Augmented values will be displayed for each five degrees of compass, 0-360. Find the compass bearing that most closely matches the return bearing from the station to you. We need to record one value only. Preferably, record the RMS Augmented value, if given. If not available, record the RMS Standard value. If not given, record the RMS Theoretical value. These values are in millivolts per meter and are the value of signal level the station presents towards you.

A quick definition of RMS Standard and RMS Augmented values. RMS Standard is essentially the RMS Theoretical value plus 5%. It is a "guard" against interference to other co-channel stations by overstating the RMS Theoretical calculated value. If stations have pattern augmentations, and many do, the RMS Augmented field will be present. Augmentations are enhancements or detractions to the theoretical pattern.

I'll use WXXI-1370 for the example. At night it runs 4 towers and has a roughly figure-8 pattern north-south. WXXI's return bearing to me is 204.7 degrees. Checking the FCC pattern plot for the station, we see that the 205 degree return azimuth presents a facing RMS Theoretical of 350.59 mV/m and a facing RMS Standard of 368.88 mV/m. We will use the RMS Standard value in the final calculation.

The theoretical pattern is used to create the standard pattern. Augmentations (if any) expand the standard pattern in specified directions. See Sections 73.150 and 73.152 of the FCC's Rules.

AM coverage may not mirror the pattern shown here. Additional factors such as ground conductivity or skywave propagation affect how far the AM signal will travel.

Patterns for stations outside the USA are based on notified parameters.

AM directional patterns created before 1982 used units of 1 mV/m at 1 mile, not one kilometer. The pattern values on such plots at 1 mile will be 0.62137 of the values listed here. Measured pattern values may vary from values shown here.

Plot is best printed on 11" by 17" or larger paper.

mV/m for single tower.

A special case requiring a simple calculation. We will calculate the mV/m figure from the RMS Theoretical value.

Again go to the FCC's web page for the facility (station), as above. The RMS Theoretical value will be on this page.

Note again that stations may have more than one entry on the page, one for each service they operate under, i.e., UNLIMITED, DAYTIME, NIGHTTIME, CRITICAL HOURS. Be sure you are looking at the correct service. Sometimes stations use a different number of towers for day and night.

The FCC computes all RMS Theoretical values from a formula of course. The values are calculated for a distance of 1 kilometer. The FCC formula used generates accurate millivolt per meter values (as published) for multiple tower arrays. Single tower arrays are a special case, however, in that the published mV/m value is always based on a 1 kilowatt output power calculation. Hence, the only published single tower mV/m values we can use are those of 1 KW stations. For all others, we will do a simple calculation to arrive at the correct mV/m value. Proof of this is simple. For example, check the FCC's published figures for my local WHAM-1180 station out of Rochester, NY. This 50KW station shows a calculated RMS Theoretical value at 1 kilometer of only 376.59 mV/m. Now of course this cannot be correct for a 50KW station, as a 1 KW station running a quarter wave (.250 wavelength) monopole has an exact calculated figure of 305.768 mV/m at 1 kilometer.

376.59 mV/m would, however, be correct for a 1 KW station using the same single tower antenna that WHAM uses (a .492 wavelength antenna).

To accurately calculate the mV/m figure for WHAM (or any other single tower station, including those 1 KW stations), the following formula must be applied:

(Power in KW, distance in KM):

mV/m = RMSTheoretical x SQRoot(Power/Distance)

Thus in WHAM's case:

2662.89 = 376.59 * SQRoot(50/1)

WHAM's actual RMS Theoretical value is 2662.89 mV/m. And since it is a single tower antenna having an

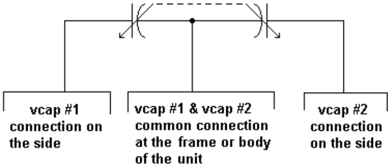
How to Hook Up A Variable Capacitor: Two Gang Capacitors

by Darrel Boyd

http://www.crystalradio.net/beginners2/caphookup.shtml



This is the typical wiring for a two gang vcap
Refer to photo below

Next, we shall compute the bandwidths at three frequencies: 530kHz, 1MHz and 1.7MHz. Results are tabulated below.

Freq.(kHz)	BW (kHz)	Q	R_P (kΩ)	A (kΩ)	C (pF)	Ca (pF)	r (Ω)	L_1 (uH)
530	5.004	105.9	354.32	155.50	450	200	30	152
1000	13.47	74.24	558.7	190	100	200	30	152
1700	24.83	68.49	487.072	406.8	31	200	30	152

Results for BW are very close to those obtained from simulation of circuit of Fig.1.b.

---

omnidirectional pattern, it presents this value of signal in all directions. Use the value you calculate for your single tower station of interest as the mV/m value that the station presents towards you.

Making The Calculation

Now we have all of our information. Let's get busy. We will use the FCC's Ground Wave Field Strength Versus Distance graph to arrive at the received mV/m signal level. Proceed with the following steps.

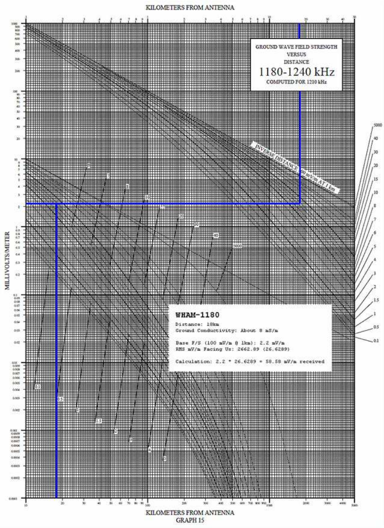
1. To make them universal, the FCC's Ground Wave Field Strength Versus Distance graphs are based on 100 mV/m levels at 1 kilometer. We simply need to calculate how many 100s our mV/m value is. Just move the decimal point left two places. In WHAM's case, 2662.89 mV/m, 26.6289 (26.6289 x 100 = 2662.89). The multiplier value we will use for WHAM is 26.6289. In WXXI's case, 368.88 mV/m, 3.6888 (3.6888 x 100 = 368.88). The multiplier value we will use for WXXI is 3.6888.

2. Find the station distance in kilometers on the graph, usually at the bottom. The bottom range is 10 to 1000 kilometers. The top range is 0.1 to 50 kilometers.

3. Draw a trace upwards (or downwards if using the top scale) until you hit the ground conductivity value curve that matches the average ground conductivity between you and the station.

4. From the previous point, draw a trace leftward to the scale on the left side of the graph. This is the base millivolt per meter level based on 100 mV/m at 1 kilometer. Multiply this value by your multiplier value. In WHAM's case, multiply times 26.6289. In WXXI's case, multiply times 3.6888. This

resultant value is the received field strength in millivolts per meter at your location.



There you have it. You have ballparked the approximate field strength of your station of interest. If done correctly, you should find this in fairly good agreement with V-Soft's figure

---

$$2L_1[C_T + C(1 \pm \omega_r C_T R_e)]\Delta\omega = \pm C_T R_e \left(\frac{Ca}{2Ca + C}\right)$$

Now, if $\omega_r C_T R_e \ll 1$, then:

$$2\Delta\omega = \pm \frac{R_e}{L_1}\left(\frac{C_T}{C_T + C}\right)\left(\frac{Ca}{2Ca + C}\right)$$

this is:

$$\Delta\omega = \pm \frac{R_e}{2L_1}\left(\frac{Ca}{2Ca + C}\right)\left(\frac{Ca}{2Ca + C}\right)$$

$$= \pm \frac{R_{s1}}{L_{eq}}\left(\frac{Ca}{2Ca + C}\right) \qquad \dots(2)$$

From part II of our study we can obtain the following expression for R_{s1}:

$$R_{s1} = r\left(1 + \frac{A}{R_P}\right)$$

Then, the 3dB bandwidth is given by:

$$BW = 2\Delta\omega = 2r\left(1 + \frac{A}{R_P}\right)\left(\frac{1}{L_1\left(2 + \frac{C}{Ca}\right)}\right)\left(\frac{Ca}{2Ca + C}\right) \qquad \dots(3)$$

in radians per second.

or:

$$\frac{\omega L_1}{1-\omega^2 L_1 C} - \frac{1}{\omega C_T} = \pm R_e \qquad \ldots(1)$$

Let ω_r be the resonant frequency and $\omega = \omega_r + \Delta\omega$ the frequency at a –3dB point on the amplitude curve. The left hand member of eq. (1) can be written as:

$$\frac{\omega^2 L_1(C_T+C)-1}{(1-\omega^2 L_1 C)\omega C_T} = \frac{(\omega_r^{\ 2}+2\omega_r\Delta\omega)(C_T+C)L_1-1}{(1-(\omega_r^{\ 2}+2\omega_r\Delta\omega)L_1 C)\omega_r C_T}$$

with the following approximations:

$$(\omega_r+\Delta\omega)C_T \approx \omega_r C_T$$

$$(\omega_r+\Delta\omega)^2 = \omega_r^{\ 2}+2\omega_r\Delta\omega+\Delta\omega^2 \approx \omega_r^{\ 2}+2\omega_r\Delta\omega$$

Then:

$$\frac{\omega_r^{\ 2} L_1(C_T+C)+2\omega_r(C_T+C)L_1\Delta\omega-1}{(1-\omega_r^{\ 2}L_1 C-2\omega_r L_1 C\Delta\omega)\omega_r C_T} = \pm R_e$$

or:

$$\frac{2\omega_r(C_T+C)L_1\Delta\omega}{\left(\dfrac{Ca}{2Ca+C}\right)-2\omega_r L_1 C\Delta\omega} = \pm\omega_r C_T R_e$$

which simplifies to:

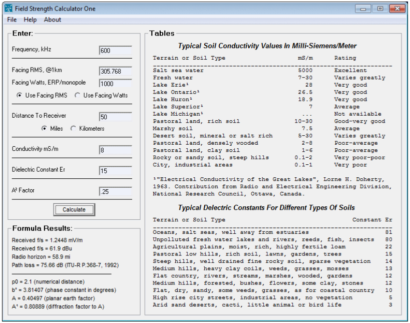
if you are near the zipcode point they based their calculation on. With a list of expected receive field strengths for various stations, you can judge the approximate sensitivity of your receiver. After a few times trying this, you will find the calculation to be rather simple to do.

PART IV: Field Strength Calculator One

http://radio-timetraveller.blogspot.com/2012/12/field-strength-calculator-one.html

20 December, 2012

Field Strength Calculator One is a program which will calculate expected received ground wave signal strength at longwave and mediumwave frequencies.



Frequency, kHz 600

Facing RMS, @1km 305.768

Facing Watts, ERP/monopole 1000

● Use Facing RMS ○ Use Facing Watts

Distance To Receiver 50

● Miles ○ Kilometers

Conductivity mS/m 8

Dielectric Constant Er 15

A² Factor .25

Formula Results:

Received f/s = 1.2448 mV/m
Received f/s = 61.9 dBu
Radio horizon = 58.9 mi
Path loss = 75.66 dB (ITU-R P.368-7, 1992)

p0 = 2.1 (numerical distance)
b° = 3.81407 (phase constant in degrees)
A = 0.40497 (planar earth factor)
A¹ = 0.80889 (diffraction factor to A)

Typical Soil Conductivity Values In Milli-Siemens/Meter

Terrain or Soil Type	mS/m	Rating
Salt sea water	5000	Excellent
Fresh water	7-30	Varies greatly
Lake Erie¹	28	Very good
Lake Ontario¹	26.5	Very good
Lake Huron¹	18.9	Very good
Lake Superior¹	7	Average
Lake Michigan¹	...	Not available
Pastoral land, rich soil	10-30	Good-very good
Marshy soil	7.5	Average
Desert soil, mineral or salt rich	5-30	Varies greatly
Pastoral land, densely wooded	2-8	Poor-average
Pastoral land, clay soil	1-6	Poor-average
Rocky or sandy soil, steep hills	0.1-2	Very poor-poor
City, industrial areas	0.1-1	Very poor

¹"Electrical Conductivity of the Great Lakes", Lorne H. Doherty, 1963. Contribution from Radio and Electrical Engineering Division, National Research Council, Ottawa, Canada.

Typical Delectric Constants For Different Types Of Soils

Terrain or Soil Type	Constant Er
Oceans, salt seas, well away from estuaries	81
Unpolluted fresh water lakes and rivers, reeds, fish, insects	80
Agricultural plains, moist, rich, highly fertile loam	22
Pastoral low hills, rich soil, lawns, gardens, trees	15
Steep hills, well drained fine rocky soil, sparse vegetation	14
Medium hills, heavy clay coils, weeds, grasses, mosses	13
Flat country, rivers, streams, marshes, wooded, gardens	12
Medium hills, forested, bushes, flowers, some clay, stones	12
Flat, dry, sandy, some weeds, grasses, as for coastal country	10
High rise city streets, industrial areas, no vegetation	5
Arid sand deserts, cacti, little animal or bird life	3

DISCUSSION

Being a mediumwave DXer and particularly a daytime mediumwave DXer, I wanted a way to determine a "ballpark" signal strength for various stations not only in my immediate area, but out to 100, 200, or even more miles distant. I was unhappy with virtually all the web-based signal strength calculators found on the internet, as they use the vanilla Inverse-Square-Law to calculate signal attenuation. Fine, if you are in an outer space vacuum or on a perfecting conducting surface, but not even close in accuracy for normal people here on Mother Earth.

The few stand-alone programs out there were either wildly expensive, too complicated to use, inaccessible, or plainly won't work on the Windows platform. I set out to accumulate information, formulas, and data to start writing the field strength calculator program. Investigating the history and ferreting out the pertinent information to arrive at a simplified formula that was reasonably accurate took some time.

The result was and is Field Strength Calculator One. It is based on the work of numerous engineers and mathematicians, who, starting about 1909, spent some 50 years developing the extremely complicated formulas to predict accurate signal strength at mediumwave frequencies. The basic, simplified formula has been known since the 1930s, being slightly

---

We shall now proceed to calculate the 3dB bandwidth of circuit of Fig.1.b.
Mesh current is given by:

$$I = \frac{E_a}{R_e + j\left(\frac{\omega L_1}{1-\omega^2 L_1 C} - \frac{1}{\omega C_T}\right)}$$

where:

$$C_T = \frac{CaC}{Ca + C}$$

The amplitude-frequency relationship for I is determined by:

$$I(\omega) = \frac{E_a}{\sqrt{R_e{}^2 + \left(\frac{\omega L_1}{1-\omega^2 L_1 C} - \frac{1}{\omega C_T}\right)^2}}$$

At the -3dB points:

$$I(\omega) = \frac{E_a}{\sqrt{2}R_e}$$

The corresponding frequencies must satisfy the equation:

$$R_e{}^2 + \left(\frac{\omega L_1}{1-\omega^2 L_1 C} - \frac{1}{\omega C_T}\right)^2 = 2R_e{}^2$$

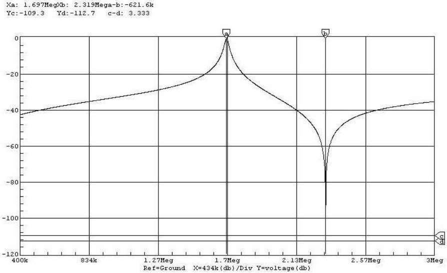

Fig.3.e Frequency response for circuit of Fig.1.b when resonance is adjusted to 1.7MHz

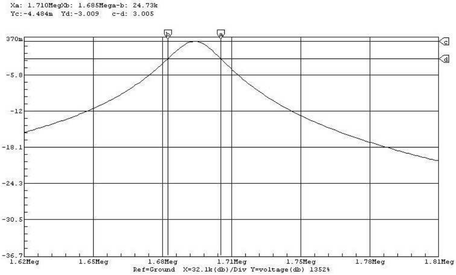

Fig.3.f 3dB bandwidth for a resonance frequency of 1.7MHz is 24.73kHz

3dB bandwidth calculations

modified by various people and agencies since then. It is accurate to within a couple of percent of the big programs that calculate field strength - those using additional input like the transmit and receive array heights above average ground, and the earth's topographic elevation changes along the signal path.

Simplified ground wave electrical field intensity calculations can be made by the introduction of a shadow or diffraction factor in the Sommerfeld-Norton planar earth expression. A mouthful! This simply means that a factor is computed and introduced to account for the additional attenuation caused by wave diffraction out beyond the radio horizon. It permits one to calculate the ground wave E (electrical) field well beyond the geometric and radio horizon, where E field values are close to the atmospheric noise level.

Be sure to read about the history of how this fascinating formula came about in the recent article on RADIO-TIMETRAVELLER: Field Strength Calculations: A History. Many of the terms used in the previous and next paragraphs are explained.

The simplified formula used by Field Strength Calculator One takes into account Sommerfeld's original plane earth theory, modified by diffraction factoring. It uses an exponential function which takes into account the spherical earth diffraction effects, and acts on the planar earth equation even before the radio horizon is reached, so the resultant E field values, as a function of distance produce a continuous curve, thus rounding-in difficult intermediate distances.

The long-accepted concept of "numerical distance" (p0) and "phase angle" (b) are used in all calculations, two variables determined by frequency, distance, and dielectric constants of the ground as a radio conductor. Numerical distance depends not only on frequency and ground constants, but also on the actual distance to the transmitter. Phase angle is the measure of the power factor angle of the earth.

Field Strength Calculator One returns expected received field strength in millivolts per meter and dBu (also known as dBµV/m), based on ground conductivity, earth dielectric and several other input constants. It also displays the distance to the radio horizon and the signal path loss in dB, along with several more technical parameters. The resulting output of Field Strength Calculator One should be accurate in most cases to a couple of percent in the longwave and mediumwave bands. It compares favorably to ITU program GRWAVE and currently available FCC Ground Wave Conductivity graphs.

Field strength calculations by Field Strength Calculator One are based on the works of A.Sommerfeld (1909), B.Rolf (1930), K.A.Norton (1936), H.Bremmer (1949, 1958), NTIA Report 86-203 (1986), ITU-R P.368-7 (1992), and NTIA Report 99-368 (1999).

For further information on how field strength is calculated see the Field Strength Calculations Series previously published on RADIO-TIMETRAVELLER.

ANTENNA AND GROUND SYSTEM

by Kenneth A. Kuhn

http://www.kennethkuhn.com/students/crystal_radios/antenna_and_ground_system.pdf

Introduction

This article explains the basics of the antenna and ground system for a crystal radio and the associated mathematical model. The mathematical model tells us how to design the antenna input section of the radio for optimum performance.

The passing RF wave induces an RF voltage across a length of wire referred to as an antenna. The induced voltage is the signal strength in volts/meter multiplied by the electrical (not the physical) height of the antenna in meters. For antennas that are shorter than one-quarter wavelength the electrical height is roughly the wire length (including lead-in wire) in meters. There are very little directivity effects for short antennas so orientation is not really a factor –i.e. the antenna is omnidirectional. The physical height of the antenna above the earth affects the signal amplitude as there is increased attenuation of the signal close to the ground.

The antenna should be as long as practical and as high as practical. A quarter wavelength for 540 kHz is (300,000/4)/540 = 139 meters. A quarter-wavelength at 1700 kHz is 44 meters. For a basic crystal radio there is little to be gained by an antenna longer than about 40 meters or higher than about 8 meters –that is a substantial antenna that few have the room to construct. A minimum antenna might be about 10 meters long and about 3 meters off the ground. Anything in-between can produce acceptable performance. Advanced crystal radio enthusiasts will construct bigger and more advanced antennas but that involves a degree of engineering beyond the scope of this article.

One advanced method that the author has not had the space to try is a true dipole antenna that is one-half wavelength long (in some cases longer). Such an antenna is balanced and so does not depend on a low-impedance ground for operation. The power received by the antenna would be significantly more than that of the simple long wire antennas described in this article. With such an antenna a local station could drive a speaker to significant volume. But, the antenna is only useful over a narrow band of frequencies and is also directive so it must be oriented properly relative to the transmitting antenna.

Figure 1 shows a typical antenna and ground setup for a crystal radio. The following sections discuss each attribute.

Figures 3.a through 3.f show simulation results for circuit of Fig.1.b at resonance frequencies also of 530kHz, 1MHz and 1.7MHz. Again, r = 30 ohms and Ca = 200pF.
Re = $2Rs_1$, and it can be easily shown that:

$$R_{s1} = r\left(1 + \frac{A}{R_p}\right)$$

The Y axis on the graphics represents voltage across Re in decibels, with Ea being a 1 volt-amplitude unmodulated carrier.

Figure 1: Basic Antenna System for a Crystal Radio

Distal support

If available, a tree makes a convenient support for the antenna wire. Otherwise some kind of post will have to be constructed. Never use a utility pole or any other support that is not your property –your potential liabilities could be astronomical if some accident (lightning for example) or failure causes damage to someone else’s property or person. An insulator typically made of ceramic or plastic is used to terminate the antenna wire and to connect to the antenna support usually via some kind of rope. These insulators are readily available from various hobby electronics sources. A large wood screw typically with a hook or eye end driven into a tree or other support is used as an attachment point for the rope. Do not wrap the rope around the tree as that will constrict growth in future years.

Antenna wire

The antenna wire is typically #14 AWG solid or stranded copper wire and may or may not be insulated. Insulation has no effect on reception but is an advantage to reduce corrosion effects. There is no advantage to using heavier wire such as #12 or #10 as the resistance of the wire is negligible compared to everything else and the added weight makes the end supports more challenging. Wire sizes of #16 and #18 also work well but are less strong –but are also lighter and will put less stress on the supports. Wire gauge sizes higher than 18 are not recommended because they are more fragile and are hard to see if they fall –you would like to not run over the wire with a lawn mower –could be very disastrous! Although low resistance is nice, it is a myth to go to great efforts for low resistance in the antenna wire as the resistance of the ground is going to be considerably higher.

The height of the antenna absolutely must be above head level for someone who might be standing on some vehicle (i.e. bicycle or motorcycle) that might possibly travel under the antenna to prevent what could be a horrible or even tragic accident –this means at least 3 meters. The antenna wire should not pass over anything such as a road or other wires such as electrical power such that if the antenna fell that a dangerous situation could result. Within practical limits the higher the antenna the more signal it will pick up. That does not extend indefinitely and there is a point of diminishing returns reached at roughly 5 meters. If it is easy for you to make the antenna higher then do so but there is little point in going to great effort to achieve that as you will only notice a difference in the extreme small signal case.

frequency of 1MHz is 13.78kHz

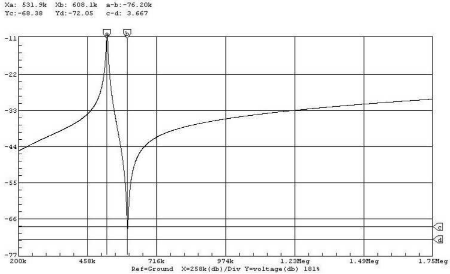

Fig.2.a Frequency response of circuit of Fig.1.a
when resonance is adjusted to 530kHz

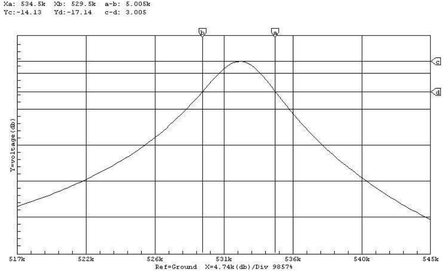

Fig.2.b 3dB bandwidth for a nominal
resonance frequency of 530kHz is 5.005kHz.
Actually, the resonance frequency is 532kHz.

Proximal support

This support is similar to the distal support and may be attached to either the dwelling or a convenient tree that happens to be close. An insulator supports the antenna and rope. The lead-in wire attaches to the antenna at the insulator. It is important to make sure that the support can break away without damaging the structure should something fall on the antenna wire.

Lead-in wire

The lead-in wire can be whatever is convenient and is often #18 wire. Since the antenna system is much shorter than one-quarter wavelength the lead-in counts as part of the antenna length. Thus, if the antenna wire was 25 meters and the lead-in wire was 5 meters, the total antenna length would be 30 meters.

Lightning arrestor

A lightning arrestor is an important part of the antenna system that is located outside the building and usually close to where the antenna and ground wires penetrate. A lightning arrestor consists of a spark gap that will arc when more than a few hundred volts exists across the points. Contrary to the name, a lightning arrestor will not protect you or the dwelling from a direct lighting strike. A lightning arrestor will reduce the probability of damage to your crystal set and anything nearby should lightning strike in the vicinity. A nearby strike can induce many hundreds or even thousands of volts on the antenna that could cause damage or injury. The lightning arrestor will then arc to limit the voltage to typically several tens of volts. You should never operate a crystal radio if there is any possibility of a lightning strike. A number of people install shorting switches or connections to connect the antenna to ground when the radio is not being used. This provides some measure of safety but is not absolute. Nothing can protect you or your dwelling from a direct lightning strike.

Ground wire and ground system

The ground wire is typically #18 copper (because that is a convenient size) and should connect to either a nearby metal water pipe or some ground system –either buried pipe or ground rod(s). It is a myth to use wide braid or other large conductor for the ground wire as the resistance of a short length of #18 is negligibly small in comparison to the earth. It is nice for the wire to be no longer than necessary because inductive reactance in the wire can interfere with the operation of the radio –but that is a small point.

Most difficulties or frustrations with crystal radios can be traced to a poor ground system. Building a good ground system is the most labor intensive and even most expensive part of a crystal radio. If you are lucky then there is a long metal water pipe located just outside the window of your crystal radio. In that special case your ground system is easy and cheap.

If you are not so lucky then one alternative is to drive three or more 2.4 meter (8 foot) ground rods straight into the ground near the house. These should be spaced roughly 2 meters apart. The quality of this ground can vary a lot depending on soil conditions and it is not likely to be as good as that of a water pipe. At the easiest, this is a very labor intensive to even impossible job if the ground is very hard. A heavy duty hammer drill can make the job easier. Otherwise you will need

Simulation results

Figures 2.a through 2.f illustrate simulation results for circuit of Fig.1.a at resonance frequencies of 530kHz, 1MHz and 1.7MHz. Assumed values for r and Ca are 30 ohms and 200pF, respectively. The values for R_T are those obtained when the secondary load R_2 is impedance matched to the primary side (please refer to part II). Notch frequencies occurring above resonance can be observed on the graphics. The Y axis represents voltage across r in decibels with Ea being a 1volt-amplitude unmodulated carrier.

Analysis of the Tuggle Front End – Part III

As a first approximation, the 3dB bandwidth of the antenna-ground-lossy tuner system under matched load conditions can be computed assuming that the L_1-C tank behaves as an equivalent constant inductance Leq in the 3dB passband, this inductance being in series with the rest of the circuit. However, this approach leads to large errors in the results, as suggested by a SPICE circuit simulation.

A precise model for accurate bandwidth computation is shown in Fig.1.a below. R_T is the net RF resistance in parallel with the L_1-C tank at $\omega = \omega_r$, as found in part II of our study. Ground losses Rg and antenna radiation resistance r_a are accounted for by r. However, calculations on this circuit are rather tedious. Simulation shows that the circuit depicted in Fig.1.b can be alternatively employed for bandwidth computation with equivalent results to those given by the circuit of Fig.1.a. Here, Re = $2Rs_1$ (please refer to part II). Circuit calculations in this case are much more simple.

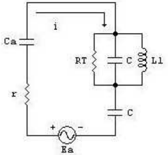

Fig.1.a Equivalent circuit for accurate 3dB bandwidth calculation

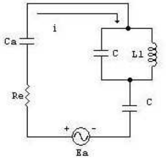

Fig.1.b Alternative circuit for bandwidth calculation as suggested by simulation

---

a very heavy sledge hammer and strong and enduring muscles as well as significant patience.

An alternative is to dig a shallow trench at least 0.2 meters deep and bury a 10 meter or more length of copper pipe. It helps for the soil to be wet down to the level of the pipe when the radio is being used. This can make a decent ground for radio reception although it should in no way be considered a “safety” ground.

The following table provides a general idea of the quality of the ground system.

Ground Quality	Resistance
Excellent	< 10 ohms
Good	10 to 20 ohms
Fair	20 to 40 ohms
Poor	40 to 100 ohms
Bad	> 100 ohms

A good question is how to measure the ground resistance. This is kind of hard to do since you have access to only one wire. Where is the other end that we measure with respect to? The answer is that it is nebulous but there does exist an effective point that completes the circuit for the radio signal. The effective ground resistance can be inferred from measurements using a received signal. The method is discussed in another chapter. Mathematical model of the antenna and ground system

A simple electrical model of a short wire antenna less than one-quarter wavelength is shown in Figure 2. It consists of a voltage source equal to the induced amplitude with a small series resistance and very large series capacitive reactance. A simple electrical model of the ground circuit is a series resistance that may range from single digit ohms (an excellent ground) to several tens of ohms. A poor ground may have a series resistance of over one hundred ohms.

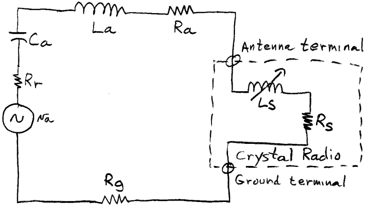

Figure 2: Simple Circuit Model for Antenna and Ground

Signal pickup

The radio frequency field strength is measured in volts/meter (or amperes/meter if you divide volts/meter by the free space impedance of 377 ohms). This is a cyclic voltage gradient. The voltage that will be induced in a conductor that is short in comparison to a quarter wavelength is roughly the RF signal multiplied by the length of the conductor. Proximity of the conductor to other conductive objects (such as trees and the earth) will reduce the induced voltage. This is one reason why it is desirable for the antenna to be as high as practical above the earth. There is no difference between the antenna proper and the lead-in so the total length is what counts. In Figure 2 this voltage is shown as Va.

Comments:

The values obtained for the coupling coefficient K hold for $R_2 = \frac{R_{TNK}}{3}$, as discussed previously. The transformed antenna-ground system resonance resistance, as seen from the secondary, will be equal to R_2, or $\frac{R_{TNK}}{3}$, as we are dealing with maximum power transfer to R_2. Under these conditions, the loaded Q of the secondary circuit will be 1/6 of the unloaded value. For other load conditions, the respective data should be entered into eq.(9).

f = 530 kHz
L_1 = 152 uH
Ca = 200 pF (assumed)
r = 30 ohms (assumed)
A = 1.555 x 10^5 ohms
Q_1Q_2A = 2.938 x 10^{10} ohms
K = 4.165 x 10^{-3}
Check:

Q_1Q_2A = 2.334 x 10^{10} ohms
K = 5.663 x 10^{-3}
Check:

$$\frac{R_P}{1+K^2Q_1Q_2} = 113.1 kohms >> \omega_r L_{eq} = 2.387 kohms$$

f = 1.7 MHz
L_1 = 152 uH
Ca = 200 pF (assumed)
r = 30 ohms (assumed)
A = 4.068 x 10^5 ohms
Q_1Q_2A = 1.29 x 10^{10} ohms
K = 8.324 x 10^{-3}

Check:

$$\frac{R_P}{1+K^2Q_1Q_2} = 152 kohms >> \omega_r L_{eq} = 3.498 kohms$$

Radiation resistance

There is an effective radiation resistance associated with the total antenna length. For electrically short antennas this may only be a few ohms but can rise to several tens of ohms as the antenna length approaches one quarter wavelength. In Figure 2 this resistance is shown as rr.

Antenna reactance

An antenna has both a series capacitance and series inductance that makes up a net reactance that varies with wavelength. Capacitive reactance dominates if the antenna is shorter than one-quarter wavelength and inductive reactance dominates between one quarter and one-half wavelength at which capacitive reactance dominates again for the next quarter wavelength, etc. Normal antennas for crystal radios are significantly shorter than one-quarter wavelength so there is a large capacitive reactance in series with the induced voltage. The inductive reactance reduces the net reactance somewhat for short antennas. At quarter-wave resonance the reactance terms cancel and the antenna is purely resistive. In Figure 2 these are shown as Ca and La.

Antenna resistance

The antenna wire has electrical resistance that is mainly due to the skin effect of the conductor since the frequency is high. This resistance is typically a few ohms and is often small in comparison with the ground resistance. In Figure 2 the antenna wire resistance is shown as Ra.

Antenna tuner inductance

The first element typically found in a crystal radio is an adjustable inductor to neutralize the capacitive reactance of the antenna thus maximizing the power transfer from the antenna to the receiver input resistance. This is known as conjugate matching where the sum of the positive inductive reactance of the inductor and negative capacitive reactance of the antenna is zero. In Figure 2 this inductance is shown as Ls for series inductance.

Crystal radio input resistance

The crystal radio generally appears as a pure resistance at resonance with a received signal. For optimum power transfer this resistance should be equal to the sum of the ground plus antenna plus radiation resistance. The ground resistance typically dominates this equation. The input resistance of the radio can be adjusted via taps on the tuning inductor or other matching network. For best performance it is important to match the radio to the antenna and ground system. Failure to do this results in an underperforming radio.

Ground resistance

The ground resistance completes the circuit back to the rather nebulous point that is the effective reference for the radio frequency signal. Ideally, this resistance is less than 10 ohms but typically is in the 10 to 100 ohm range.

A single short wire antenna is unbalanced and a low-impedance ground is required to complete the RF circuit. It is easy to set up a simple wire antenna that can work well but it is a challenge to construct a low-impedance ground. Without a low-impedance ground much of the signal picked up by the

---

Some experimental results

Two coils, L_1 and L_2, were wound on 4.5” diameter styrene forms using 660/46 Litz wire. L_1 measured 152 uH and L_2, 222 uH. A two-gang 475 pF variable capacitor with bakelite insulation was used to tune L_1. L_2 was tuned with a 480 pF variable capacitor with ceramic insulators.
Unloaded Qs for each of the tuned circuits were measured at three frequencies. Accordingly, the corresponding RF losses were calculated. Data is tabulated below.

f	Q_1	Q_{2UL}	Q_2	R_{Pcalc}	$R_{TNKcalc}$	C	C_2
530kHz	700	810	270	354.32 kohms	598.816 kohms	450 pF	406 pF
1 MHz	585	630	210	558.70 kohms	878.766 kohms	100 pF	114 pF
1.7 MHz	300	318	106	487.072 kohms	754.065 kohms	31 pF	39.5 pF

C : two-gang 475 pF variable capacitor with bakelite insulation
C_2 : 480 pF variable capacitor with ceramic insulation
Q_{2UL} : unloaded Q of L_2-C_2 combination
Q_1, Q_2 : defined in the text
R_P, R_{TNK}: defined in the text

Using the tabulated data, values for the optimum coupling coefficient K will be calculated for a working crystal set.

$$R_{s1} = (\omega_r L_{eq})^2 \left(\frac{N^2 L_2}{L_1}\right)\left(\frac{Q_1 Q_2}{R_P}\right)$$

$$= (\omega_r L_{eq})^2 \left(\frac{N^2 L_2}{L_1}\right)\left(\frac{1}{\omega_r L_1}\right)\left(\frac{R_2}{\omega_r L_2}\right)$$

$$= \left(\frac{L_{eq}}{L_1}\right)^2 N^2 R_2$$

$$= \left(\frac{2Ca + C}{Ca}\right)^2 N^2 R_2$$

or:

$$N^2 R_2 = \left(\frac{Ca}{2Ca + C}\right)^2 R_{s1}$$

Substituting this equivalence into eq.(13):

$$P_2 = \frac{{E_a}^2}{8R_{s1}} = P_{MAX}$$

according to eq.(10).

P_{MAX} is then dissipated by N^2R_2 and by consequence, this power is delivered to the secondary load.

antenna will be wasted and the crystal radio will perform poorly if at all. Much frustration from poor performance of a crystal radio set is often caused by a high-impedance ground. An ideal situation is to connect the crystal radio set to a metal water pipe (either old-fashioned galvanized or preferably copper). The long exposure length to the earth produces a low-impedance ground in the low tens of ohms. The impedance is even lower if the soil is very organic and wet from a recent rain. Dry sandy soils are the worst. One common error is connecting to a metal water pipe assuming that there are no plastic pipe lengths involved.

If a metal water pipe is not available then it might be tempting to connect to the ground system of the electrical distribution in the house or building. For safety considerations I do not recommend this. In the vast majority of cases it may be alright but you never know what errors or faults may be in the system that could result in a nasty or lethal surprise. Even if safety were not an issue, because of inductance the impedance of the ground system at radio frequencies will be much higher than the impedance at 60 Hz. So, this practice is dangerous at worst or is not likely to work well at best. There are basically only two choices for constructing your own ground. One is to purchase several standard eight foot ground rods and laboriously install them spaced six or more feet apart. This can make a decent ground but is very difficult (impossible is probably more accurate) without the right equipment for installation. An easier alternative that is fine for RF (although not recommended for 60 Hz systems) is to bury a length of bare copper wire or pipe perhaps six to twelve inches below the surface of the ground. Deeper is better but the incremental improvement is probably not worth the extra labor. The total length should be fifty feet or more and parallel runs spaced several feet apart can be used to accumulate effective length. AM broadcast stations use such a system with many buried radial wires from the tower. Each wire is typically a quarter wavelength and the total wire length of all the radials is often over a mile. Such extreme measures are necessary for a high power transmitter because otherwise many thousands of watts could be wasted. The much more modest system described is fine for home use and a point of diminishing returns is quickly reached.

Figure __ shows the theoretical radiation resistance for a single wire antenna that is shorter than one-half wavelength calculated under the assumption that there are no nearby objects that interfere with the impedance. For most situations the antenna is not very far above the ground and the actual resistance will likely be somewhat less than shown. But this is a reasonable model to use for analysis.

Figure __ shows the theoretical series capacitive reactance

How much signal can be received? With a variety of impedance transformations we can obtain most any voltage or current we want but what really matters is how much power we can receive. It is power that will make audible sounds in our earphones. Assuming that there are no losses and that the load consists of an inductor with the same magnitude of reactance as the antenna capacitive reactance in series with a resistive load equal to the radiation resistance of the antenna, then the power delivered to the resistive load is:

P = (V/m/2 * L)^2 /(40*pi^2*L^2*FMHz^2 /300^2)

= (V/m)^2 *57 / FMHz^2

$$R_{s1} = \left(\omega_r L_{eq}\right)^2 \frac{K^2 Q_1 Q_2}{R_P} \quad \ldots(12)$$

Then:

$$\frac{\omega_r L_{eq} K^2 Q_2}{R_{s1}} = \frac{R_P}{\omega_r L_{eq} Q_1}$$

$$= \frac{L_1}{L_{eq}}$$

$$= \frac{Ca}{2Ca + C}$$

Then, we obtain:

$$E_2{}' = \frac{E_a}{2}\left(\frac{Ca}{2Ca + C}\right)$$

The power dissipated by N^2R_2 is:

$$P_2 = \frac{\left(E_2{}'\right)^2}{2N^2 R_2}$$

$$= \frac{\left(\frac{E_a}{2}\right)^2 \left(\frac{Ca}{2Ca + C}\right)^2}{2N^2 R_2} \quad \ldots(13)$$

Eq.(12) can be written as follows:

$$E_2' = \frac{E_{Leq}}{j\omega_r L_1 + N^2 R_2} N^2 R_2$$

In crystal sets, $N^2 R_2 << \omega_r L_1$, due to the loose coupling between L_1 and L_2. Then:

$$E_2' = \frac{E_{Leq}}{j\omega_r L_1} N^2 R_2$$

$$= \frac{E_{Leq}}{j\omega_r L_1}\left[\frac{(\omega_r L_1)^2}{R_{P1}}\right]$$

$$= \frac{E_{Leq}}{jR_{P1}}\omega_r L_1$$

Bearing in mind eq.(3):

$$E_2' = \frac{E_{Leq}}{j} K^2 Q_2$$

Substituting the value of E_{Leq} given by eq.(11) into the above expression we obtain:

$$E_2' = \frac{E_a}{2R_{s1}}\omega_r L_{eq} K^2 Q_2$$

We can recall that:

MATHEMATICAL MODEL OF A WIRE ANTENNA

by Kenneth A. Kuhn

www.kennethkuhn.com/.../mathematical_model_of_wire_antenna.pdf

Introduction

Although very simple in structure, the mathematical model of a wire antenna is extremely complicated. There are so many variables that it is basically impossible to accurately model. However, a reasonable model can be derived that provides useful information and understanding. That is essential for doing engineering. An imperfect model is far better than no model. We begin with the simplest possible model (that is always a good starting point!). Then, we refine the model to include more advanced concepts. We keep refining until we have accounted for all significant variables that provides useful information.

A wire antenna consists of some length of wire at some height over the earth. Such a structure will have some capacitance to the earth, some inductance, and some resistance. The resistance term is more complicated than just the simple ohmic resistance of the wire as it includes a series term known as radiation resistance. In very simple terms radiation resistance accounts for a flow of energy between the antenna and free space involving time-dependent electromagnetic fields not considered in a simple RLC circuit. Our initial model is based on frequencies much less than that where the antenna is one-quarter wavelength resonant. For typical crystal radio applications this is not a bad model as it is rare to have the luxury of enough space to construct an antenna approaching one-quarter wavelength in the AM broadcast band.

Capacitance

We start with the capacitance of the antenna to the earth. From the basic laws of physics, a capacitance will exist between any two conductors separated by insulation. Here, we are making the rather crude assumption that the earth is a good conductor. That turns out not to be bad as we will see that the reactance of this capacitance at frequencies in the AM broadcast band is large compared to the actual resistance of the earth. A brief but excellent derivation of the capacitance between a cylinder (i.e. the antenna wire) and a plane is provided in Reference 1. The summary result is:

$$\text{Capacitance per meter} = \frac{2 * \pi * \varepsilon 0}{\ln(2 * \text{height} / \text{diameter})} \quad \text{Eq. 1}$$

where height and wire diameter are in meters and ε0 is the permittivity of free space, 8.85 pF/meter. Note that this equation assumes that propagation time over the wire length is negligibly small. This equation also assumes that the earth is a perfect conductor.

Although there is an error when considering the composite antenna, there is no error for an incremental portion that satisfies the assumptions.

A quick example indicates that a 20 meter antenna of #14 wire (1.63 mm dia.) at a height of 3 meters would have a total capacitance of 135 pF at frequencies low enough so that the propagation time over the length is negligibly small. That is not true for broadcast band frequencies and the capacitance will be smaller as will be seen in the plots at the end.

Inductance

$$K = \sqrt{\frac{R_P + A}{Q_1 Q_2 A}} \qquad \ldots(9)$$

which gives the value of the coupling coefficient for maximum RF power transfer to the secondary.

Power calculations

The RF power delivered to the secondary load of Fig.1 will be at a maximum at resonance when eq.(6) is satisfied, this is, when r + $R_s = R_{s1}$. The maximum available power is then:

$$P_{MAX} = \frac{\left(\frac{E_a}{2}\right)^2}{2R_{s1}}$$

$$= \frac{E_a{}^2}{8R_{s1}} \qquad \ldots(10)$$

where E_a is the peak value of the voltage induced in the antenna.

The power delivered to the secondary load R_2 is the same as that dissipated by the coupled resistance N^2R_2. To compute this power we need the voltage across L_1 at resonance. This is the same as the voltage across L_{eq} in Fig.6.a. Then:

$$E_{Leq} = \frac{E_a}{2R_{s1}} j\omega_r L_{eq} \qquad \ldots(11)$$

From Fig.5 we obtain for the voltage across N^2R_2:

$$= L_1\left(2+\frac{C}{Ca}\right) \quad \ldots(7)$$

being

$$\omega_r^{\ 2} = \frac{1}{L_1 C}\left(\frac{Ca+C}{2Ca+C}\right)$$

Then:

$$\left(\omega_r L_{eq}\right)^2 = \frac{1}{L_1 C}\left(\frac{Ca+C}{2Ca+C}\right)L_1^{\ 2}\left(\frac{2Ca+C}{Ca}\right)^2$$

$$= \frac{L_1}{C}\left(2+\frac{C}{Ca}\right)\left(1+\frac{C}{Ca}\right)$$

Eq.(6) is now written as:

$$\frac{L_1}{rC}\left(2+\frac{C}{Ca}\right)\left(1+\frac{C}{Ca}\right) = \frac{R_P}{K^2 Q_1 Q_2 - 1} \quad \ldots(8)$$

Letting $A = \frac{L_1}{rC}\left(2+\frac{C}{Ca}\right)\left(1+\frac{C}{Ca}\right)$, eq.(8) takes the more compact form:

$$A = \frac{R_P}{K^2 Q_1 Q_2 - 1}$$

Solving for K we obtain:

On page 141 of Reference 1 the inductance of a wire over a plane is given as

$$\text{inductance per meter} = \frac{\mu 0}{2 * \pi} * \ln(2*\text{height} / \text{diameter}) \quad \text{Eq. 2}$$

where height and wire diameter are in meters and μ0 is the permeability of free space, 4*π*1E-07 henries/meter. Equation 2 simplifies to

inductance per meter = (0.2 uH) * ln(2*height / diameter) Eq. 3

A quick example indicates that a 20 meter antenna of #14 wire (1.63 mm dia.) at a height of 3 meters would have a total inductance of 33 uH if propagation time is negligibly small. Note that Equation 2 assumes that the current is uniform over the length of the wire and that propagation time is negligibly small. The first part of the assumption can not be true for our antenna as the far end is an open circuit. The equation also assumes that the earth is a perfect conductor. The typical error for our use in antennas for crystal radios falls into the category of not bad. We are not going to worry about it as this is just a starting point and we are going to make refinements. Although there is an error when considering the composite antenna, there is no error for an incremental portion that satisfies the assumptions.

Resistance

The resistance of a wire antenna is the sum of the ohmic resistance including skin effect and the radiation resistance. The resistance of #14 wire including skin effect at a frequency of 1 MHz is around 0.05 ohms per meter. Thus a 20 meter antenna would have a total resistance of 1 ohm. This assumes that the current is uniform over the length which can not really be true since the far end is an open circuit. However, this is not going to be an issue for us as the resistance of the ground will be significantly larger.

The ohmic resistance represents a power loss. Radiation resistance becomes a factor when we consider the coupling of energy between the antenna and electromagnetic fields of free space. The concept is easy to understand in the case of a transmitter which delivers power to the antenna (perhaps significant power in the case of a 50 kW transmitter!) but with efficient design the heating of the antenna is very small –i.e. the power is radiated as an electromagnetic wave instead of being converted to heat –i.e. power is coupled to free space. The transmitter delivers the power to the antenna as some voltage and some in-phase current. Thus, the antenna appears to have a resistance. That resistance is known as the radiation resistance. Unlike ohmic resistance, it does not represent a power loss –it represents a power coupling to free space instead. There is no magic or optimum value for antenna impedance. However, values between single digit ohms and several hundred ohms are the easiest to interface to and so are preferred.

It is not as easy to visualize radiation resistance when the antenna is used for reception. However, the concept of reciprocity applies. Thus, however an antenna appears in the transmitting case, it appears identically in the receiving case. The calculation of radiation resistance is very complicated at the easiest. At this point in our model development we have no way to determine what the radiation resistance of our antenna might be. However, the incremental capacitance and inductance are essential for the next level model.

$$= (\omega_r L_{eq})^2 \left(\frac{1 + K^2 Q_1 Q_2}{R_P} \right)$$

$$= \frac{(\omega_r L_{eq})^2}{R_P} + (\omega_r L_{eq})^2 \frac{K^2 Q_1 Q_2}{R_P}$$

Let $R_s = \frac{(\omega_r L_{eq})^2}{R_P}$ and $R_{s1} = (\omega_r L_{eq})^2 \frac{K^2 Q_1 Q_2}{R_P}$.

R_s is the series term due to R_P and R_{s1}, that coming from the coupled resistance N^2R_2. Now, maximum RF power transfer to N^2R_2 occurs when:

$$r + R_s = R_{s1}$$

or when:

$$r + \frac{(\omega_r L_{eq})^2}{R_P} = (\omega_r L_{eq})^2 \frac{K^2 Q_1 Q_2}{R_P}$$

or

$$\frac{(\omega_r L_{eq})^2}{r} = \frac{R_P}{K^2 Q_1 Q_2 - 1} \qquad \ldots(6)$$

From part I of this study we know that:

$$L_{eq} = \frac{L_1}{1 - \omega_r^2 L_1 C}$$

If $R_T >> \omega_r L_{eq} = \dfrac{\omega_r L_1}{1-\omega_r^{\,2} L_1 C}$ (please refer to part I of this study) we can redraw the equivalent circuit of the tuner at resonance as indicated by Fig.6.a, and, by virtue of the above inequality, the resonant frequency ω_r will still be given by:

$$\omega_r^{\,2} L_1 C\left(\frac{2Ca + C}{Ca + C}\right) = 1 \qquad \ldots(5)$$

Applying a parallel-to-series transformation, the equivalent circuit of Fig.6.b is obtained.

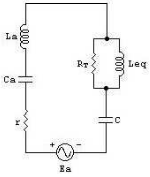

Fig.6.a Equivalent circuit of the tuner when $R_T >> \omega_r Leq$

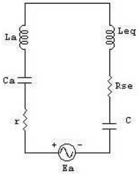

Fig.6.b Equivalent circuit after transformation

The series transformed resistance R_{se} is given by:

$$R_{se} = \frac{(\omega_r L_{eq})^2}{R_T}$$

A finite propagation time model

This model is based on well-developed transmission line theory and treats the wire antenna as a lossy unterminated transmission line where the loss is electromagnetic radiation instead of heat. This model builds on the previous equations for capacitance and inductance and gives us a realistic picture of what goes on. In general, because there are a lot of variables that we are unable to quantify the accuracy of this model is not great. However, the model can be tweaked to provide a good fit to a specific scenario. That is what makes the model useful. It is great at providing us general information for understanding. Understanding what is going on can be more valuable than knowing specific data accurately.

The impedance looking into a transmission line is

$$Z = Z0 * \frac{(ZT/Z0) + \tanh(\alpha + j\theta)}{1 + (ZT/Z0) * \tanh(\alpha + j\theta)} \qquad \text{Eq. 4}$$

where:
Z is in ohms and is in general complex.
Z0 is the characteristic impedance of the line –often taken as real but could be complex.
ZT is the termination impedance at the end of the line and could be complex.
α is the loss over the length of the line.
θis the phase angle on the line and is equal to 2*π*length/wavelength.
j is the square root of -1.

The form of the equation I have chosen to use includes length in the α and θ terms as a matter of convenience. Other forms of the equation have the length as a multiplier on the inside of the tanh term.

If the terminating impedance is an open circuit as it will be for our wire antenna then we can write Equation 4 simply as

Z = Z0 / [tanh(α + jθ)] Eq. 5

For reference:

ex –e-x
tanh(x) = ----------- Eq. 6
ex + e-x

The Euler relations are:

ejθ = cos(θ) + j*sin(θ) Eq. 7

e-jθ = cos(θ) – j*sin(θ) Eq. 8

These relations let us write Equation 5 as

eα+jθ + e-α-jθ
Z = Z0 * ----------------
eα+jθ–e-α-jθ

eα* [cos(θ) + j*sin(θ)] + e-α* [cos(θ) –j*sin(θ)]
= Z0 * ---
eα * [cos(θ) + j*sin(θ)] –e-α* [cos(θ) –j*sin(θ)]

(eα+ e-α)*cos(θ) + j*(eα–e-α)*sin(θ)
= Z0 * -- Eq. 9
(eα–e-α)*cos(θ) –j*(eα+ e-α)*sin(θ)

Let $Q_2 = \frac{R_2}{\omega_r L_2}$. Then:

$$R_{P1} = \frac{\omega_r L_1}{K^2 Q_2} \qquad \ldots(3)$$

Next, we compute the equivalent resistance R_T of the parallel combination of R_P and R_{P1}. It is given by:

$$R_T = \frac{R_P R_{P1}}{R_P + R_{P1}}$$

Substituting R_{P1} by its equivalent given by eq.(3):

$$R_T = \frac{R_P\left(\frac{\omega_r L_1}{K^2 Q_2}\right)}{R_P + \frac{\omega_r L_1}{K^2 Q_2}}$$

$$= \frac{R_P \omega_r L_1}{\omega_r L_1 + K^2 Q_2 R_P}$$

Letting $Q_1 = \frac{R_P}{\omega_r L_1}$ (unloaded Q of L_1-C tank) we obtain:

$$R_T = \frac{R_P}{1 + K^2 Q_1 Q_2} \qquad \ldots(4)$$

Up to this point, in the tuner side we have the equivalent circuit depicted in Fig.5.

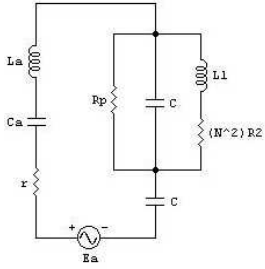

Fig.5 Equivalent circuit of the tuner with coupled secondary load

The series-coupled resistance N^2R_2 can be transformed into a resistance R_{P1} in parallel with R_P. Using the known series-to-parallel "loss resistance" transformation we get:

$$R_{P1} = \frac{(\omega_r L_1)^2}{N^2 R_2} \qquad \ldots(2)$$

Although Equation 9 looks complicated it really consists of just three components and it is simple to substitute values and reduce it to a simple real plus imaginary result.

For reference: Eq. 10

$$\frac{A + jB}{C + jD} = \frac{A + jB}{C + jD} * \frac{C - jD}{C - jD} = \frac{AC + BD}{C2 + D2} + j\frac{BC - AD}{C2 + D2}$$

Equation 10 gives us a basic method to evaluate the division of complex numbers.

When the series and shunt losses are low the characteristic impedance of a transmission line is

Z0 = sqrt(inductance per unit length / capacitance per unit length) Eq. 11

We substitute Equations 1 and 2 into Equation 11 to obtain

$$Z0 = \text{sqrt}\left[\frac{\left[\frac{\mu 0}{2 * \pi} * \ln(2*\text{height} / \text{diameter})\right]}{\left[\frac{2*\pi*\varepsilon 0}{\ln(2*\text{height} / \text{diameter})}\right]}\right] \qquad \text{Eq. 12}$$

which simplifies to

Z0 = 60.0 * ln(2*height / diameter) Eq. 13

Thus, we make use of our previous work on the simple model.

The free-space wavelength in meters for a given frequency in MHz is

$\lambda = 300 / \text{FMHz}$ Eq. 14

The propagation velocity on wire antennas is about 95 percent of free space so we use

$\lambda = 285 / \text{FMHz}$ Eq. 15

$\theta = 2*\pi*\text{FMHz}*\text{length} / 285$ Eq. 16

So far this has not been too complicated. Now, we delve into the challenge of determining the remaining constant, α. This factor, which is a function of frequency, will determine the antenna impedance characteristics. There is no way to calculate this factor. Instead, we will use available information to fit an approximate equation to it. We begin by noting that the free space impedance of a half-wave dipole antenna is 73 ohms. Our wire antenna is only half of a dipole so the free space impedance will be nominally 37 ohms (rounded half of 73) at a frequency where the wire length is an electrical one-quarter wavelength.

However, our antenna is very close to the ground so the result must be modified. Reference 2 shows a theoretical plot of the impedance of a half-wave dipole over a perfectly conducting plane as a function of height. This plot is reproduced below.

In the transformer circuit, the impedance coupled to the primary side consists of a capacitance C_2 / N^2 in parallel with a resistance N^2R_2. Both are in parallel with the magnetizing inductance K^2L_1 (please see Fig.4.a).

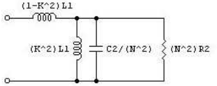

Fig.4.a Equivalent circuit as seen from the primary side

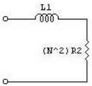

Fig.4.b Reduced equivalent at $\omega = \omega_r$

K^2L_1 and C_2 / N^2 resonate at a frequency

$$\omega_0 = \frac{1}{\sqrt{K^2 L_1 \left(\frac{C_2}{N^2} \right)}}$$

$$= \frac{1}{\sqrt{L_2 C_2}} = \omega_r$$

as

$$N^2 = K^2 \frac{L_1}{L_2}.$$

The equivalent circuit of Fig.4.a reduces to that of Fig.4.b, taking into account that for crystal set use, normally K<<1.

In this case, the net parallel resistance to be coupled to the primary is:

$$R_2 = \frac{R_{TNK}\left(\frac{R_{TNK}}{2}\right)}{R_{TNK} + \left(\frac{R_{TNK}}{2}\right)}$$

$$= \frac{R_{TNK}}{3} \qquad \ldots(1)$$

We shall work on this later.

Some circuit equivalents

In Fig.1, let´s replace L_1 and the coupled secondary circuit by the equivalent shown in Fig.3.a, which in turn can be replaced by the transformer circuit shown in Fig.3.b.

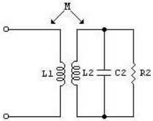

Fig.3.a Magnetically coupled circuits

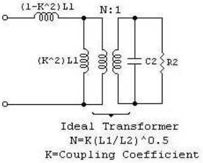

Fig.3.b Equivalent transformer circuit

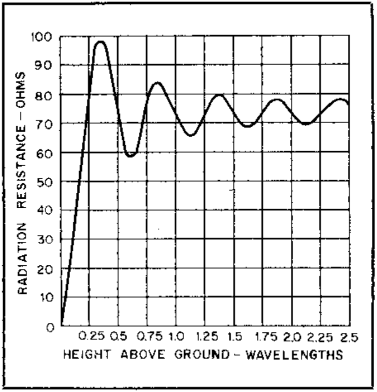

Figure 1: Theoretical impedance of half-wave dipole over perfect ground plane

Reference 2 describes that the impedance of a half-wave dipole over a realistic ground is very little affected by height over about one-half wavelength and the impedance soon attains the 73 ohm free space value.

We will use a simplified exponential to provide us with an approximate impedance of our antenna at the one-quarter wave resonant frequency. We first need a relation that converts the physical height of our antenna to height in wavelengths at the quarter-wave resonant frequency. This is provided by the following relation.

h/λ= height / wavelength = height * FMHz / 300 Eq. 17

$R = 37 * (1 - e-k1*h/\lambda)$ Eq. 18

The k1 value is chosen to be 7 because that provides the best least squares fit over the first 0.2 wavelengths of height. We can write this as

$R = 37 * (1 - e-0.02333*height*FMHz)$ Eq. 19

Equation 19 provides us with a target to set the appropriate value for α. At the frequency where the line length is one-quarter wave resonant, the cosine term in Equation 9 goes to zero and the sine term goes to one. This produces a real result with the imaginary part zero. It should be noted for this case that:

$A = 0$

$B = e\alpha - e-\alpha$

$C = 0$

$D = 2$

Using Equation 10 the above results in a resistance of

$R = Z0 * (e\alpha - e-\alpha) / 2 = Z0 * \sinh(\alpha)$ Eq. 20

We invert Equation 20 to obtain the required value for a for a given value of R as follows

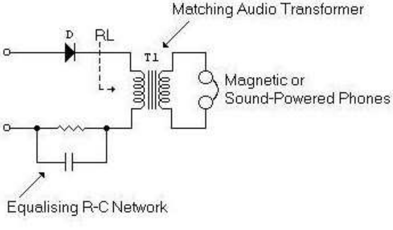

Fig. 2 Load coupled to the Tuggle tuner

Usually, it is assumed that optimum RF power transfer occurs when the antenna-ground system resonance resistance r is matched to the unloaded-secondary resonance parallel resistance R_{TNK}, with the diode detector´s input resistance matched to this combination. Thus,

$$\frac{1}{R_{OPT}} = \frac{1}{R_{TNK}} + \frac{1}{R_{TNK}} + \frac{1}{\left(\frac{R_{TNK}}{2}\right)}$$

or

$$R_{OPT} = \frac{R_{TNK}}{4} .$$

This is the overall parallel RF resistance of the secondary tank under matched conditions, and suggests that the unloaded Q of this tank circuit has been reduced to ¼ of its value.

Analysis of the Tuggle Front End – Part II

We shall now consider the Tuggle tuner delivering power to a load. First, we must account for the parallel RF losses of the unloaded tuned circuits. Let R_P represent the losses of the tank circuit comprising L_1 and C, and R_{TNK} those of L_2 and C_2 (please see Fig. 1).

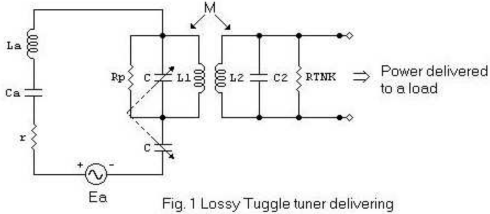

Fig. 1 Lossy Tuggle tuner delivering power to the secondary load

The load consists of a diode detector D in series with an audio load R_L (usually an audio transformer matching a pair of 2k ohms DC resistance magnetic headphones or low-impedance sound powered phones to the detector) and is coupled to the tuner via the magnetic coupling existing between L_1 and L_2, being M the mutual inductance of the coils. The secondary is tuned to the same radian frequency as the primary. An schematic for the load can be seen in Fig. 2.

α= sinh-1(R/Z0) = ln[(R/Z0) + sqrt[(R/Z0)2 + 1)]] Eq. 21

Before continuing, let us review where we are at. We know Z0 from the height and diameter of the antenna wire. We know a target resistance, R, for the antenna impedance at the one-quarter wave resonant frequency based on the height. Equation 21 lets us calculate α for that frequency. We need to expand this so that we can calculate the appropriate α for any frequency.

We make use of the following general knowledge about wire antennas to complete our model. At frequencies well below the one-quarter wave resonance the resistive component of the antenna impedance is practically zero. At frequencies where the antenna is many quarter wavelengths long the resistive component of the antenna impedance converges to Z0. This suggests that we have a basic scale factor on α and a multiplier based on the number of quarter wavelengths are on the line. This leads us to Eq. 22

α= k0 * Z0 * 37 * (1 –e-0.02333*height*FMHz) * (F / Fq)
where:

k0 is a constant to achieve the target quarter-wave resonant impedance
Z0 is the characteristic impedance of the antenna
height is in meters
F is the frequency in MHz

Fq = (71.25 / length) and is the frequency in MHz where the antenna is one-quarter wave resonant

The only unknown in Equation 22 is k0. We calculate k0 when F is equal to Fq. The procedure is as follows:

First we set FMHz = Fq from the above relation

R = 37 * (1 –e-0.02333*height*FMHz) Eq. 19

Z0 = 60.0 * ln(2*height / diameter) Eq. 13

α= sinh-1(R/Z0) = ln[(R/Z0) + sqrt[(R/Z0)2 + 1)]] Eq. 21

k0 = α/ (Z0 * R) Eq. 23

Studies done with this equation indicated very good results as long as the frequency was greater than the quarter-wave resonance. For lower frequencies this model gave very poor results –indicating significantly higher impedance than reality and even a negative slope in some cases. A modifier to the model was needed to highly attenuate αfor low frequencies only. The factor, (1 –1/(1 + 0.14*(F/Fq)2+ 1.0*(F/Fq)3 + 0.79*(F/Fq)4 + 50*(F/Fq)24)), was determined to significantly improve results. The factors were derived from a least squares fit to an alternative equation for short dipoles provided by reference 3 –shown below modified for only half a dipole.

R = 40*π2*(L/λ)2 Eq. 24

where L is the antenna length and λ is the wavelength, both in meters. This equation is reported to give good results up to about 0.2 wavelengths. A plot showing the fitted model to Equation 24 is shown below. Note that the model has an excellent fit to the theoretical "correct" model for wavelengths shorter than 0.2. The "correct" model under predicts the resistance for longer wavelengths and the effect of the 24th power term comes into play to bring the resistance close to the theoretical 37 ohms at 0.25 wavelengths. This is not exactly what goes on but is a simple to work with fit.

The circuit will tune up to:

$$f_{MAX} = f_{MIN}\left(\frac{C_{eqMAX}}{C_{eqMIN}}\right)^{\frac{1}{2}}$$

$$= 2.128MHz$$

If we use for C a variable capacitance with
C_{MIN} = 20 pF and C_{MAX} = 365 pF, then
C_{eqMIN} = 38.18 pF and C_{eqMAX} = 494.20 pF, giving for the required inductance L a value of 182.46 uH. The circuit will tune up to f_{MAX} = 1.906 MHz.

Acknowledgements: Special thanks are given to Ben Tongue for his comments on the manuscript and for encouraging further mathematical analysis of the circuit regarding bandwidth variation with frequency, which will be done shortly.

After some algebraic manipulation we obtain:

$$\omega_r^{\,2} LC\left(\frac{2Ca+C}{Ca+C}\right)=1 \qquad \ldots(3)$$

The equivalent capacitance resonating with L is:

$$C_{eq}=C\left(\frac{2Ca+C}{Ca+C}\right)$$

Clearly, $C_{eq}>C$.

Following is a numerical example illustrating the use of the above results.
Let C be a variable capacitance with
C_{MIN} = 20 pF and C_{MAX} = 475 pF.
Let also C_a be 200 pF.
Then, C_{eq} varies between
C_{eqMIN} = 38.18 pF and C_{eqMAX} = 615.74 pF.

If we wish to tune the MW broadcast band starting at 530 kHz, then the required inductance L will be:

$$L=\frac{1}{\omega_{rMIN}^{\;\;2} C_{eqMAX}}$$

$$=146.45uH$$

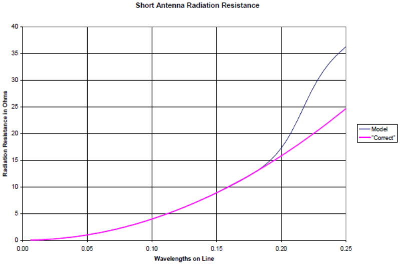

Figure 2: Model fit to short antenna radiation resistance

The complete equation for α is (using n = F/Fq) is shown below. Eq. 25

α= k0*Z0*37*(1 –e-0.02333*height*F)*n*

                    1
(1 - --)
     1 + 0.14*n2 + 1.0*n3 + 0.79*n4 + 50*n24

To calculate the approximate impedance of the antenna for any frequency we first compute the αfactor for the frequency using Equation 25. Then we compute the positive and negative exponentials using α. Next, we compute theta using Equation 16 and then the cosine and sine terms. We substitute these values into Equation 9 and use Equation 10 to solve. This is best done in a spread sheet for a range of frequencies and the results plotted. A wide range plot showing multiple quarter-wave resonances for a wire antenna is shown in Figure 3.

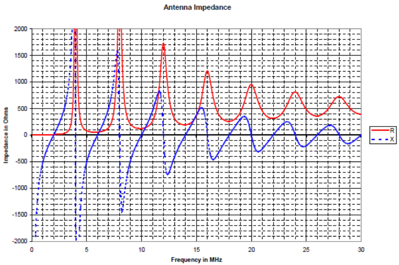

Figure 3: 2 MHz resonate antenna 5 meters off ground

The computed impedance at 2 MHz of this antenna is 7.5 ohms. The impedance at the third harmonic (6 MHz) is 55 ohms –for both resonant frequencies the reactive part is zero. It should be observed that the impedance is at a minimum and purely resistive at odd harmonics of the quarter-wave resonance. The impedance is very high at even harmonics. This figure should be viewed as illustrative rather than accurate. Although the pattern of impedance variations is true, the magnitude could vary considerably depending on actual ground conditions and the proximity of other structures. It is true that the impedance variations become smoother as the number of quarter-waves increases. Only a minimal attempt has been made to correctly model that for this model as the primary interest is in the sub quarter-wave region. More work will be done on the high frequency region at a later date. It is expected that the required effect can be obtained by the appropriate exponent on the n term that immediately follows the exponential in Eq. 25 –but some kind of short power series might be required instead. Example Antennas

This is, when:

…(2)

$$\omega\left(La+\frac{L}{1-\omega^{2}LC}\right)-\frac{1}{\omega\left(\frac{CaC}{Ca+C}\right)}=0$$

which is satisfied at certain radian frequency ω_r.
At this frequency, the L-C tank circuit behaves as an equivalent inductance

$$\frac{L}{1-\omega_r^{\,2}LC}$$

Usually, L is much greater than L_a for antennas used in crystal set work. Then,

$$La<<\frac{L}{1-\omega_r^{\,2}LC}$$

Equation (2) can be written as:

$$\frac{\omega_r L}{1-\omega_r^{\,2}LC}-\frac{1}{\omega_r\left(\frac{CaC}{Ca+C}\right)}=0$$

We can then write:

$$\frac{\omega_r L}{1-\omega_r^{\,2}LC}=\frac{Ca+C}{\omega_r CaC}$$

$$I = \frac{Ea}{r + j\left(\omega La - \frac{1}{\omega Ca}\right) + \bar{Z} - \frac{j}{\omega C}} \qquad \ldots(1)$$

$$\bar{Z} = \frac{1}{\bar{Y}}$$

where:

$$\bar{Y} = \frac{1}{j\omega L} + j\omega C$$

$$= j\left(\omega C - \frac{1}{\omega L}\right)$$

$$= j\left(\frac{\omega^2 LC - 1}{\omega L}\right)$$

$$\therefore \qquad \bar{Z} = \frac{1}{j}\left(\frac{\omega L}{\omega^2 LC - 1}\right)$$

or:

$$\bar{Z} = j\left(\frac{\omega L}{1 - \omega^2 LC}\right)$$

Then, I = I_{MAX} when:

$$\left(\omega La - \frac{1}{\omega Ca}\right) + \left(\frac{\omega L}{1 - \omega^2 LC}\right) - \frac{1}{\omega C} = 0$$

The following plots show the typical impedance for several wire antennas. In each case #14 AWG wire was used and the solid line is the radiation resistance and the dotted line is the reactance. In all cases the radiation resistance is very low. The key feature is the capacitive reactance of the antenna.

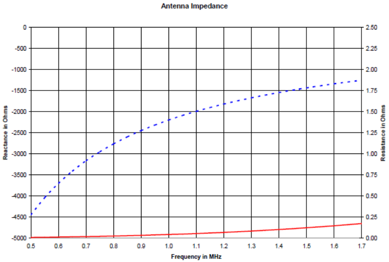

Figure 4: Antenna length = 10 m, height = 3 m

This is about as short as an antenna can be and still be practical. This antenna appears as 73 pF.

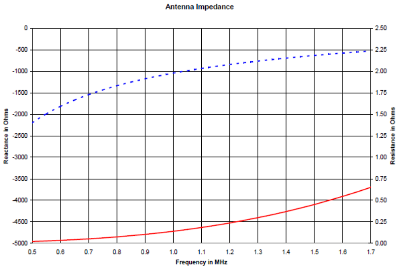

Figure 5: Antenna length = 20 m, height = 3 m

This antenna appears as 145 pF at low frequencies and 184 pF at high frequencies. The change in capacitance with frequency is because the reactance of the series inductance cancels part of the capacitive reactance.

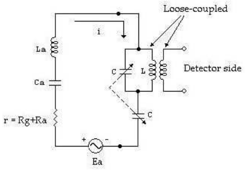
ANALYSIS OF THE TUGGLE FRONT END

By Ramon Vargas Patron

http://www.inictel-uni.edu.pe/index.php?option=com_content&view=article&id=235&Itemid=152

Part I:

This article analyzes the Tuggle tuner, of common use in high-performance DX crystal sets. An equivalent circuit for the antenna-ground system with the tuner connected is shown in Fig. 1 below. It must be recognized that there is some stray capacitance of the rotor and frame of the two-gang variable capacitor to ground. This should be shown as a fixed capacitor across the bottom variable capacitor. Its presence will reduce the maximum frequency to which the circuit will tune. However, in the present analysis this stray capacitance is neglected.



-Ea is the voltage induced in the antenna by the radio wave.
-La is the equivalent series inductance of the antenna.
-Ca is the equivalent series capacitance of the antenna.
-r accounts for the antenna radiation resistance Ra and ground losses Rg.

Fig. 1 The Tuggle front end connected to an antenna-ground system

The mesh current is described by:

Kevin Smith
09/2011

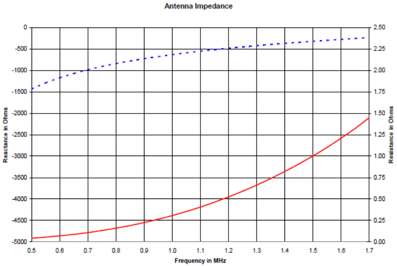

Figure 6: Antenna length = 30 m, height = 3 m

This antenna appears as 220 pF at low frequencies and 375 pF at high frequencies.

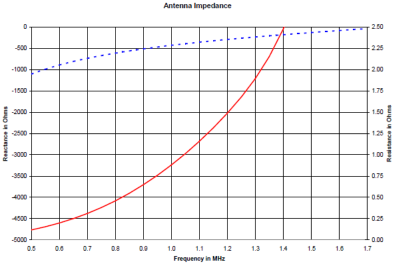

Figure 7: Antenna length = 40 m, height = 5 m

This antenna appears as 290 pF at low frequencies and is almost resonant at 1.7 MHz. This is about as long as an antenna needs to be for excellent reception. Note also that the antenna is higher. The increase in radiation resistance at higher frequencies is an indication that quarter wave resonance is being approached.

I strongly urge you to put down the Litz, set aside the silver-plated caps, store the holy-grail diodes and go do some research on your local ground. All the time, expense, and effort on the greatest "state-of-the-art" crystal receiver will be wasted if the ground is not attended to. If the resistivity of your earth is high in ohm-meters, get more metal in the ground or consider a counter-poise. The following table from LEM Instruments shows the relation between earth resistivity in ohm meters and actual earth resistance in ohms as a function of the earthing method used.

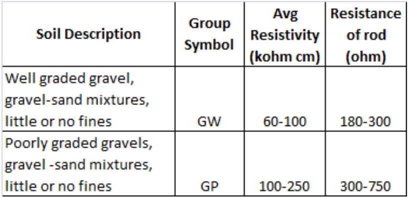
GROUNDS
by Jim Lux
http://home.earthlink.net/~jimlux/hv/grounds.htm

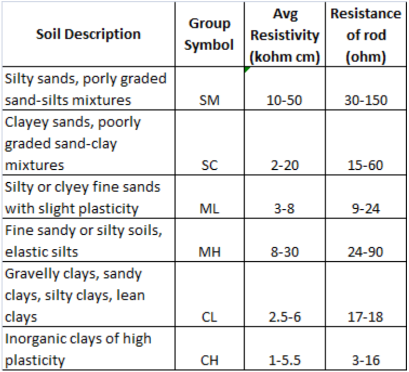
The following discussions are really applicable to line frequencies. For higher frequencies, dielectric loss must be considered, as well as skin effect. For lower frequencies (i.e. DC) consideration should be given to electrolytic effects such as polarization.

The dominant effect for a ground is the current distribution within the earth. The ground rod or wire itself typically has negligible resistance, as does the interface between the rod and soil. As such, the soil conductivity has a very large influence on the ground resistance.

Resistivity of different soils and resistance of a single rod. The rod, in the table below, is a standard rod 5/8 inch in diameter and 10 feet long (16 mm diam by 3m long) Data taken from IEEE Std 142-1991.



Soil Description	Group Symbol	Avg Resistivity (kohm cm)	Resistance of rod (ohm)
Well graded gravel, gravel-sand mixtures, little or no fines	GW	60-100	180-300
Poorly graded gravels, gravel -sand mixtures, little or no fines	GP	100-250	300-750



Soil Description	Group Symbol	Avg Resistivity (kohm cm)	Resistance of rod (ohm)
Silty sands, porly graded sand-silts mixtures	SM	10-50	30-150
Clayey sands, poorly graded sand-clay mixtures	SC	2-20	15-60
Silty or clyey fine sands with slight plasticity	ML	3-8	9-24
Fine sandy or silty soils, elastic silts	MH	8-30	24-90
Gravelly clays, sandy clays, silty clays, lean clays	CL	2.5-6	17-18
Inorganic clays of high plasticity	CH	1-5.5	3-16

Note 1) ohm M = kohm cm * 10
2) for the last two, clays, the resistivity is highly dependent on soil moisture.

Effect of Moisture Content on Soil Resistivity

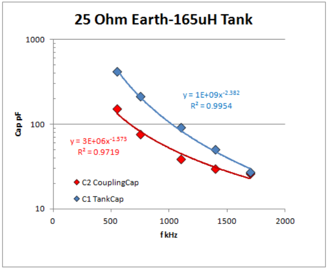
The following table gives resistivity (ohm M) for three types of soil, for moisture contents from 2% to 24% by weight. Data taken from IEEE Std 142-1991.
Note: ohm M = kohm cm * 10

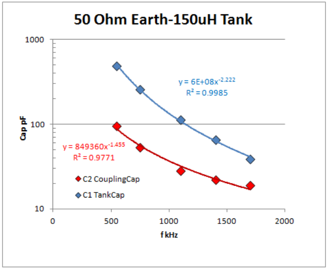
represent increasing earth resistance presented to the ATU from a very low 10 ohms to a fairly high 50 ohms. Actual earths can go up to two orders of magnitude higher. I chose L1 inductances such that the maximum needed capacitance would approach 500pFs, easily found on many variable caps. With respect to the coupling cap (C2, red curve), as the earth resistivity increases the needed capacitance declines. The tank cap value needs to resonate with the inductor and increases with smaller-value inductance. In searching for a 500pF max cap value, the choice of inductance needs to decrease with increasing earth resistance. Parameters other than Rg, L1 and C1-C2 have minor impact on the models.

Conclusions:

From the plots one can readily see that above 10 ohm earth the two variable capacitors on the ATU do not track well. As the earth resistivity increases, the worse the tracking. Most locations are not blessed with a low resistivity earth and this needs to be factored into the ATU design. There is little to be done, changing the design coil inductance will change the needed capacitance on BOTH C1 and C2, (larger L1 leads to smaller C1 and C2 for resonance and vice versa). A possible solution well worth trying is to use a dual-gang capacitor where one section has a different value than the other, the above plots give an easy way to decide the max values needed. Use the smaller gang on the coupling circuit and the larget on the tank. Experience tells us that ganging the capacitors on a "Tuggle" front end works well, but from the models I have to imagine one might squeeze a bit more performance by giving up the convenience of one-dial tuning on the ATU, especially where your earth has a fairly high resistance.

The best design concept will be to know first and critically your earth resistance. If this is just a guessed-at parameter then





The above plots show the calculated capacitance versus frequency for four different models of Earth Resistivity / Tank Inductance. In each case I maintain the same log capacitance vs frequency scale for easy comparison. The cases modeled

Effect of Temperature on Soil Resitivity
The following table gives variation in soil resistivity with temperature. The significant transition is at the freezing point, and above that the resitivity drops fairly linearly with temperature. I'm not sure about the double entry for 0 degrees.. perhaps it represents the variability at the transition temperature? Data taken from IEEE Std 142-1991.

Temperature (deg C)	Resistivity (kohm cm)
-5	70
0	30
0 (?)	10
10	8
20	7
30	6
40	5
50	4

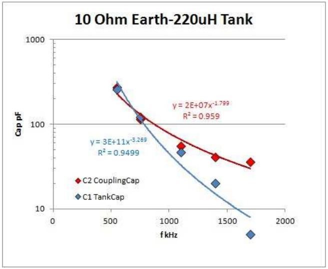
Note: ohm M = kohm cm * 10

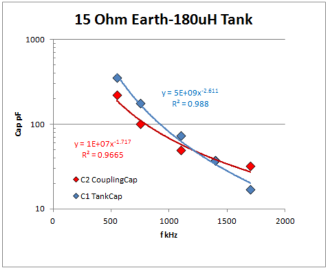
Calculation of Resistance to Earth
An expression, accurate to 15%, for a single 10ft (3m) rod 5/8" (16mm) in diameter is:
Rground(rod) = rho/335 ohms
where rho is in ohm-cm. (ohm-cm = ohm M *100)

Multiple rods

Multiple ground rods are often used particularly where high currents may be involved. The ground resistance is not simply the resistance of one rod, divided by the number of rods, unless the rods are very far apart. However, even though the ground resistance of the combination may not be all that much better than a single rod, the current is shared among the rods, reducing the current per rod. A guideline from IEEE Std 152-1991 to avoid "smoking rods" is:

Max Current(amps) = 34.8E3 * d * L / sqrt(rho * t)
where:
d is the rod diameter in meters
L is the rod length in meters
rho is the soil resistivity in **ohm meters**





1) Frequency is chosen per your interest, I have taken models at F = 550-1100-1700 kHz.

2) Coil inductance one has control over when winding. I have chosen base values that resonate with about 400pF tank capacitance, with some sensitivities.

3) Unloaded Q I do not have. For modeling I have taken Vargas's measures for a 4.5" coil wound with 660/46 Litz wire. I assume this will be about as good a coil as one can wind. I also made a sensitivity for lower Q. Q is a function of frequency and I have used the appropriate value of Q to match the modeled frequency.

4) Series Resistance is basically what the earth and ground system will deliver plus a small 1-2 ohm contribution from Ra and Rr. I have modeled four cases 10, 15, 25 and 50 ohms. The first two cases reflect my needs on the Gulf Coast with low resistivity soil. The 25 ohm case is a "typical" or "standard" grround. Finally, many will have much higher resistivity soils and you need to know just how difficult things can get!

5) Series capacitance I based for my specific antenna on the model of Ken Kuhn (Mathematical Model of Wire Antenna). The capacitance of a 30m antenna 3m high he calculated to range from 220pF and low frequencies to 375pF and high frequencies. I input the correct capacitance to match the frequency modeled.

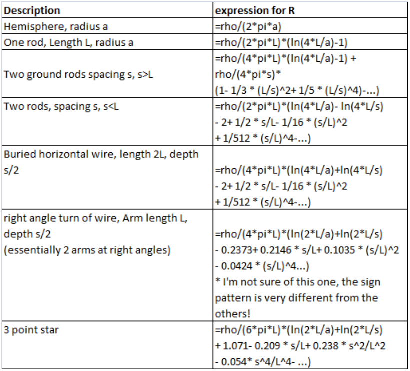
6) Series inductance I just input 20 uH every time.

The data and plots for four different scenarios follow:

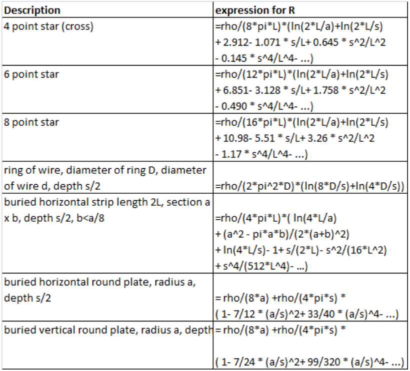
t is the duration of the current in seconds (and is valid for short times only)

The text of IEEE Std 142-1991 claims that for 1 ft 5/8" rod (32 cm x 16 mm) this expression yields 116A in 2500 ohm cm soil and 58A for 10,000 ohm-cm soil, however I don't get these numbers.

Here's a table of some formulae to calculate ground resistance for combinations of rods. This table is taken from IEEE Std 142-1991, but it's cited there as coming from: Dwight, H.B.,"Calculation of resistance to ground", *AIEE Transactions*, vol 55, Dec 1936, pp 1319-1328.



Description	**expression for R**
Hemisphere, radius a	=rho/(2*pi*a)
One rod, Length L, radius a	=rho/(2*pi*L)*(ln(4*L/a)-1)
Two ground rods spacing s, s>L	=rho/(4*pi*L)*(ln(4*L/a)-1) + rho/(4*pi*s)* (1- 1/3 * (L/s)^2+ 1/5 * (L/s)^4)-...)
Two rods, spacing s, s<L	=rho/(2*pi*L)*(ln(4*L/a)- ln(4*L/s) - 2+ 1/2 * s/L- 1/16 * (s/L)^2 + 1/512 * (s/L)^4-...)
Buried horizontal wire, length 2L, depth s/2	=rho/(4*pi*L)*(ln(4*L/a)+ln(4*L/s) - 2+ 1/2 * s/L- 1/16 * (s/L)^2 + 1/512 * (s/L)^4-...)
right angle turn of wire, Arm length L, depth s/2 (essentially 2 arms at right angles)	=rho/(4*pi*L)*(ln(2*L/a)+ln(2*L/s) - 0.2373+ 0.2146 * s/L+ 0.1035 * (s/L)^2 - 0.0424 * (s/L)^4...) * I'm not sure of this one, the sign pattern is very different from the others!
3 point star	=rho/(6*pi*L)*(ln(2*L/a)+ln(2*L/s) + 1.071- 0.209 * s/L+ 0.238 * s^2/L^2 - 0.054* s^4/L^4- ...)



Description	expression for R
4 point star (cross)	=rho/(8*pi*L)*(ln(2*L/a)+ln(2*L/s) + 2.912- 1.071 * s/L+ 0.645 * s^2/L^2 - 0.145 * s^4/L^4- ...)
6 point star	=rho/(12*pi*L)*(ln(2*L/a)+ln(2*L/s) + 6.851- 3.128 * s/L+ 1.758 * s^2/L^2 - 0.490 * s^4/L^4- ...)
8 point star	=rho/(16*pi*L)*(ln(2*L/a)+ln(2*L/s) + 10.98- 5.51 * s/L+ 3.26 * s^2/L^2 - 1.17 * s^4/L^4- ...)
ring of wire, diameter of ring D, diameter of wire d, depth s/2	=rho/(2*pi^2*D)*(ln(8*D/s)+ln(4*D/s))
buried horizontal strip length 2L, section a x b, depth s/2, b<a/8	=rho/(4*pi*L)*(ln(4*L/a) + (a^2 - pi*a*b)/(2*(a+b)^2) + ln(4*L/s)- 1+ s/(2*L)- s^2/(16*L^2) + s^4/(512*L^4)- ...)
buried horizontal round plate, radius a, depth s/2	= rho/(8*a) +rho/(4*pi*s) * (1- 7/12 * (a/s)^2+ 33/40 * (a/s)^4- ...)
buried vertical round plate, radius a, depth	= rho/(8*a) +rho/(4*pi*s) * (1- 7/24 * (a/s)^2+ 99/320 * (a/s)^4- ...)

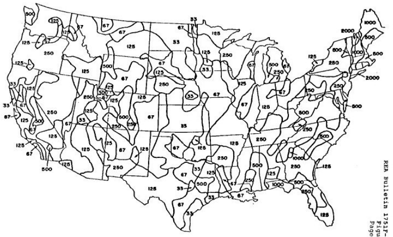

FIGURE 2

Estimated Average Earth Resistivity in U.S. (ohm-meters)

Modeling:

All the above discussion is great but... What is important really? The following section presents the results of applying different parameters to get a feel for the sensitivity of it all. To begin with I need explain my base assumptions. All the models are based on Kleijer's calculation spreadsheet which requires inputs for the following parameters:

Frequency
Coil inductance
LC circuit Q unloaded
* Complex impedance of antenna or
Series Resistance (Rg+Ra+Rr)
Series Capacitance Ca
Series Inductance La

* If the series values are given, the complex impedance is calculated.

of typical ranges in ohm meters for some different soils follows:

Loam	5	-	50	ohm meter
Clay	4	-	100	
Sand/Gravel	50	-	1,000	
Limestone	5	-	10,000	
Sandstone	20	-	2,000	
Granite	1,000	-	2,000	
Slates	600	-	5,000	

Moisture up to about 17% dramatically lowers resistivity, mineral salts are needed and pure water is an insulator, and as the temperature approaches freezing the resistivity also rises dramatically. All this factors into your estimation of Rg. The actual resistivity seen by the circuit depends on the earth resistivity and the type of grounding system you have installed. The more metal in the ground, and deeper, the lower the resistance. Know thy earth! A map of USA soil resistivity follows:

Map of Effective Ground Conductivity in the USA
REA Bulletin 1751F-802
http://www.rurdev.usda.gov/SupportDocuments/UTP_Bulletins_1751F-802.pdf

1. GENERAL

1.1 Ground, is defined as a conducting connection by which a circuit or equipment is connected to the earth. The connection is used for establishing and maintaining the potential of the earth, or approximately that potential, on the circuit or equipment connected to it. A "ground" consists of a grounding conductor, a grounding electrode, a grounding connector which attaches the grounding conductor to the ground electrode, and the soil in contact with the ground electrode.

1.2 Using Grounds in Protection Applications:

1.2.1 For natural phenomena, such as lightning, grounds are used to discharge the system of current before customer or personnel can be injured or vulnerable system components can be damaged.

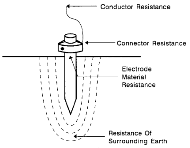
1.2.2 For potentials due to faults in electric power systems with ground return, grounds aid in ensuring rapid operation of the power system protective relays by providing additional low resistance fault current paths. The low resistance path provides the means for the removal of the potential as rapidly as possible. The ground should drain the potential before personnel are injured or the telephone system damaged.

1.3 Ground Resistance: Ideally, a ground should be of zero ohms resistance. In reality, this value cannot be obtained due to the series resistances shown in Figure 1: Components of Resistance in a Ground Connection. Grounding theory and methods for obtaining a ground of the smallest practical resistance will be discussed in subsequent paragraphs.

2. PHENOMENA AFFECTING GROUND RESISTANCE

2.1 Introduction: A grounding electrode cannot be driven into the soil with the expectation of obtaining a good, low resistance, ground. Many factors, both natural and human, may affect results. Some of the factors include:

Figure 1: Components of Resistance in a Ground Connection



Conductor Resistance
Connector Resistance
Electrode Material Resistance
Resistance Of Surrounding Earth

2.1.1 **Earth Resistivity**: The electrical resistivity of the earth (resistance of the earth to the flow of current) is of major importance. The unit of earth resistivity, the ohm·meter, is defined as the resistance, in ohms, between opposite faces of a cube of earth one cubic meter in volume. An alternative unit of measurement, the ohm·centimeter, is defined as the resistance in ohms, between opposite faces of a one centimeter cube of earth. To convert ohm·meters to ohm·centimeters, multiply by the former by 100.

2.1.1.1 Earth resistivity varies over a considerable range. Within the United States it varies from a few ohm·meters along some coasts to many thousands of ohm·meters in rocky, mountainous country. Figure 2: Estimated Average Earth Resistivity in U.S. provides very general data on average surface earth resistivity throughout the United States.

inductance L1 and capacitance C1. The capacitance and inductance of the ATU is needed to tune out the reactance of the various components of the antenna for which we do not have data. What to do?

Without an antenna analyzer (expensive) one can only estimate the many component values based on published antenna models. Ken Khun's engineering page has a number of nice models and a good discussion of the antenna parameters we will be trying to understand and use. For my personal setup my antenna consists of about 75' of 14awg wire averaging about 10-12' high and with another 25' of lead-in. For such an antenna Khun models a 30m antenna 3m high which approximates my situation closely enough. Wire resistance is negligible as is the radiation resistance which he shows to vary between some 0.1 to 1.5 ohms. Such an antenna is capacitive by nature and will have about 220 - 375pF along with some small 20uH inductance, not too far off a standard "dummy" antenna. This pretty much leaves earth resistance Rg as the main unknown parameter.

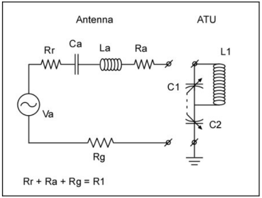
For Rg one has the option of punting and taking the "Standard" value of 25 ohms. In my modeling I have found this parameter to be critical and highly sensitive. I do not recommend guessing here, it is recommended one go to the internet page of their state, county, or local government and search for reports on ground or soil resistivity (or conductivity). As this is an important agricultural and engineering parameter, it has been surveyed for most places and should be available with some effort. Effort well rewarded. Earth resistivity for the Texas Gulf Coast is a mercifully low 10 - 15 ohm meters, but for many regions this will not be the case.

Earth resistivity depends on a number of variables including the material, moisture, mineral salt, and temperature. A table and for this I am deeply in his debt. My hat's off to Dick, thanks so much.

The following discussion presents the results of many models cranked through the design calculator. I wished to understand what factors play main roles and which have minor parts.

For a conventional detector-circuit coil one can pretty much control all the main factors, really only the inductance and capacitance of the circuit. The main and only surprise comes in the form of "stray capacitance" resulting from the spacing of the coil wires. This can readily be 1) guessed at and 2) minimized by good coil winding technique. For the antenna circuit by contrast many of the needed parameters, earth resistance, antenna capacitance and inductance, and antenna resistance in the forms of actual wire resistance and radiation resistance are, for most of us, unknown and only guessed at. The following figure illustrates the antenna and ATU with a list of the main "components" that need to be understood and/or modeled.

The Antenna Equivalent Circuit consists of an AC voltage source Va (the signal of interest), in series with some radiation resistance Rr, antenna capacitance Ca, antenna inductance La, antenna resistance Rr, and finally a ground resistance Rg for the return path to complete the circuit. In addition the ATU consists of a coupling capacitance C2, and a tank with



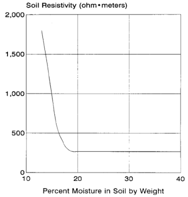
2.1.1.2 In addition to regional variations, earth resistivity may vary widely within very small distances due to local soil conditions. Table I lists typical ranges of earth resistivity for various soil types. This table should be useful in selecting locations at which a ground is to be installed.

TABLE I: RESISTIVITY OF VARIOUS SOILS

SOIL	RESISTIVITY RANGE (ohm·meters)
Loam	5 - 50
Clay	4 - 100
Sand/Gravel	50 - 1,000
Limestone	5 - 10,000
Sandstone	20 - 2,000
Granite	1,000 - 2,000
Slates	600 - 5,000

2.1.2 **Soil Moisture**: Nearly any soil, with a zero moisture content, is an insulator. Fortunately, this condition is rarely encountered except in desert areas or during periods of extreme drought. Figure 3: Typical Variation of Soil Resistivity with Moisture illustrates the typical affect of moisture on soil resistivity. It should be noted that above 17% moisture by weight additional moisture has little effect. Below this figure resistivity rises rapidly until, at 2% moisture it reaches 100 times its value at 17% moisture. Thus, a good ground connection should always be in contact with soil having a ground water content in excess of 17%. Local well drillers

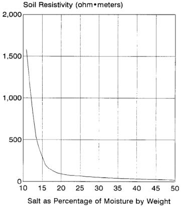
Figure 3: Typical Variation of Soil Resistivity with Moisture



should be able to provide information concerning the depth of the water table in their areas. Water content alone does not provide a good ground in many areas so do not be misled by moisture depth only. (See Soil Mineral Content section to follow).

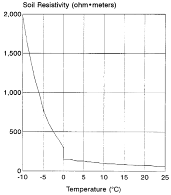
2.1.3 **Soil Mineral Content**: Water with no mineral salt content is nearly as good an insulator as soil with no moisture content. Figure 4: Typical Effect of Mineral Salt on Earth Resistivity illustrates the effect of mineral salt content on soil resistivity. Soils which lack adequate soluble mineral salts may be encountered from time to time.

Figure 4: Typical Effect of Mineral Salt on Earth Resistivity



2.1.4 **Temperature**: As the temperature of soil decreases, resistivity increases. When the soil temperature drops below the freezing point of water, resistivity increases rapidly, as shown in Figure 5: Typical Variation of Soil Resistivity with Temperature.

Figure 5: Typical Variation of Soil Resistivity with Temperature



Notes on simulations for a Tuggle Front End

http://www.lessmiths.com/~kjsmith/crystal/atu.shtml

By Kevin Smith

Introduction:

When designing my radios I always make extensive use of Mike Peebles and Dan Petersen's "Professor Coil" spreadsheet. This tool along with the many tutorials and explanations online have vastly eased the design work around homebrew coil winding. We can now model a coil with good accuracy prior to the actual job and thus better match the coil to the other components we plan to include. One quickly becomes aware that most coils for the broadcast band vary around a nominal 220 or so uH. More than this and most variable capacitors will have too much bottom-end capacitance to tune the top of the band. Less than this and you need caps with fairly high values when fully meshed, 500+pF or more.

All the above is pretty straight forward. On the other hand, when I have been reviewing double-tuned set designs, I often note that the coil used for the ATU (antenna tuning unit) will have an inductance quite a bit lower than the main tank coil. Professor Coil doesn’t address this aspect of coil design and I have found little discussion online concerning ATU design. Mostly this seems to be dealt with in passing or as a digression when dealing with other subjects. The most useful web sites for addressing this aspect of crystal set design include Dick Kleijer's excellent work and Ramon Vargas's detailed analysis of the "Tuggle Front End", that’s about it. Neither site discusses the ramifications of varying different parameters such as the Earth Resistance, Coil Inductance, etc although Kleijier's site includes a great calculator page to allow one to ask these questions. In my explorations of ATU design (primarily Tuggle) I have made extensive use of Kleijier'e page

APPENDIX C MEASUREMENT OF SOIL RESISTIVITY

1. GENERAL

1.1 Soil Resistivity Measurements are commonly made with a test instrument that uses the four-terminal fall of potential method. The test instrument has four terminals that are connected to four electrodes arranged at equal distances along a straight line (shown in Figure C1: "Four-Terminal" Method for Measurement of Soil Resistivity). Internally the instrument contains a current circuit and a voltage circuit. The current source can be a handdriven a.c. generator or a voltage reversing vibrator that causes a current to flow between the two outer electrodes (Terminals C1 and C2). A potential is measured between the inner electrodes (Terminals P1 and P2). The voltage and current circuits are coupled within the test set to provide a reading in ohms.

1.2 The Theory for This Measurement was developed by Dr. Frank Wenner of the U.S. Bureau of Standards in 1915 and published in Report No. 258, Bulletin of Bureau of Standards, Vol. 12, No. 3, October 11, 1915, "A Method of Measuring Earth Resistivity." Dr. Wenner established that, if the test electrode depth is small compared to the distance between the electrodes, the following equation applies to determine the average soil resistivity to a depth equal to the distance between the electrodes:

$\rho = 2\pi AR = 6.28AR$
Where: q = Average soil resistivity to depth equal to A, in ohm·centimeters
$\pi = 3.1416$
A = Distance between electrodes, in centimeters

R = Test instrument resistance reading, in ohms
Note: Divide ohm·centimeters by 100 to convert to ohm·meters.

1.3 Ground Test Instruments generally use an alternating voltage source with a frequency not related to power system fundamental frequencies or their harmonics. This avoids the effects of polarization and foreign earth currents which could produce erroneous results.

1.4 Objectives of Soil Resistivity Measurements: The first is to determine the type of earth connection required to provide the objective resistance to earth. The second is to define any geological limitations that might be present, such as a rock layer, that would restrict installation of the grounding system.

2. BASIC SOIL RESISTIVITY MEASUREMENT

2.1 Introduction: The depth to which the average soil resistivity is desired determines the distance (A) between the test electrodes. This distance will typically be the length of the ground electrode to be installed plus the depth below the earth's surface to which it will be driven. A measurement should be taken with test electrode spacings of one-half, one, two and four times the length of the proposed ground electrode. This will identify the presence of large deviations in the soil resistivity. Place four test electrodes along a base line in relation to the proposed vertical ground electrode location as shown in Figure C2: "Four-Terminal" Method for Measuring soil Resistivity. The test electrodes should be driven into the soil to a depth equal to A/20. Depths for test electrodes for various distances (A) are shown in Table C-I.

TABLE C-I

When we disconnect the antenna from the antenna tuner, the resonance frequency of the circuit will increase to value f2.
This is because Cp is no longer part of the tuned circuit.
f2=1/(2.pi.√(L5.C6)
The frequency shift of the circuit is equal to: f2-f

The loaded Q of the circuit
If we connect the antenna (via C4) to the LC circuit, the Q of the circuit will degrease.
The Q we have then is called the Q of the loaded circuit (or the loaded Q).
If the LC circuit is well matched to the antenna, the loaded Q will be halve the value of the unloaded Q.

Step 4
Now we have X8 we can calculate also XP with the formula:
$Xp=(R1^2 + X8^2)/X8$

XP is a capacitor which is parallel to C6.
XP represents a capacitor value of: $Cp=1/(2.pi.f.XP)$, and this is in parallel with C6

Step 5
For resonance of the circuit must apply:
$f=1/(2.pi.\sqrt{(L5.Ctotal)}$

Or:

$Ctotal = C6+CP = (1/(2.pi.f))^2/L5$ if we substract the value of CP, the value of C6 is left.

Step 6
Finally we want to know the value of C4.
We already had X8.

With the formula $XC4=X8+XL2-XC3$ we can calculate the impedance of C4.
And then with $C4= 1/(2.pi.f.XC4)$ calculate the value of C4.
Now we know all values of the matched circuit.

Sometimes, XC4 will have a negative value, in that case it is not possible to get a match by means of a variable capacitor on the place of C4.
As an alternative, we then can replace C4 by a coil with value:
$L4= -XC4/(2.pi.f)$

Frequency shift when disconnecting the antenna

Test Electrode Depths for Various Distances Between Electrodes Distance Between

Electrodes (A)		Test Electrode Depth (B)	
Feet	Meters	Inches	Centimeters
5	1.52	3.0	8
8	2.44	5.0	13
10	3.05	6.0	15
16	4.88	10.0	25
20	6.10	12.0	30
30	9.14	18.0	46
40	12.19	24.0	61
50	15.4	30.0	76

2.2 Performing the Measurement: Connect the leads from the four test electrodes to the proper terminals on the test set, C1, P1, P2 and C2. Complete the measurement as described by the manufacturer of the test equipment. Calculate the soil resistivity by the equation in Paragraph 1.2 and record results.

REA Bulletin 1751F-802
Figures
Page 59

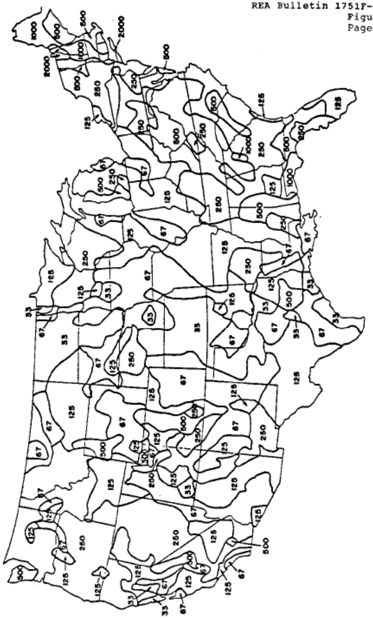


FIGURE 2

Estimated Average Earth Resistivity in U.S. (ohm meters)

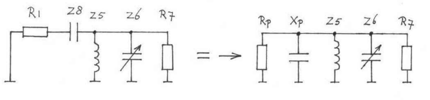
Step 2

The antenna can be considered as 3 separate components, R1, Z2 and Z3

We take the sum of Z2, Z3 and variable capacitor Z4, we consider this sum as one capacitor with impedance value Z8.

So $Z8=Z2+Z3+Z4= -JX8$

Z8 must provide the match between resistor R1 and R7



Step 3

Z8 in series with R1 can be converted to a parallel circuit RP, XP met de formulas:

$RP=(R1^2 + X8^2)/R1$ $XP=(R1^2 + X8^2)/X8$ however, we can't use these formulas yet, because X8 not known yet.

For impedance match, parallel resistor RP must be equal to parallel resistor R7.

So: $RP=R7$

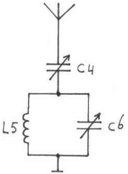
From this follows:

$$(R1^2 + X8^2)/R1 = R7$$

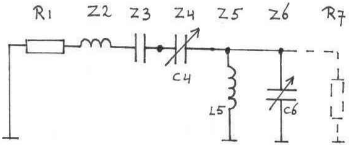
$$R1^2 + X8^2 = R7.R1$$

$$X8^2 = R7.R1 - R1^2$$

$$X8= \sqrt{(R7.R1 - R1^2)}$$



The antenna tuner



The antenna tuner split into separate impedances.
R1, Z2 and Z3 represents the antenna.
R7 is not a real resistor, but represents the losses in parallel circuit L5, C6

Step 1
Choose a frequency, calculate the complex impedance of the coil: Z5=+J(2.pi.f.L5)
Calculate the parallel resistor (R7) of the circuit L5 C6 with the formula: R7=2.pi.f.L5.Q
Resistor R7 represents the losses occurring in L5 and C6.

=Frequency without antenna (kHz)

Calculating the component values.

Here is explained what the calculator is calculating.
To calculate the component values, we need the following data:

The frequency.
The induction value of the coil (L5).
The unloaded Q of the LC circuit
The complex impedance of the antenna

The complex impedance of the antenna is build up with a certain resistor R1 which is in series with a coil (L2) and a capacitor (C3).

The values of R1, L2, and C3 are depending on many factors, like frequency, antenna length, height of antenna above ground, etc.

The impedance of the antenna is: Zantenna = R1+Z2+Z3 = R1+J(XL2 - XC3).

With a short antenna (shorter then 1/4 wavelength) XC3 will have a higher value then XL2, the result is a capacitive complex impedance for the antenna, so with a minus sign in front of the J.

How to measure the impedance of an AM-band antenna-ground system, what one can do with the results, along with some measurements

By Ben H. Tongue
http://www.bentongue.com/xtalset/20MeaAGs/20MeaAGs.html

Quick Summary: This Article describes a method to measure the series capacitive and resistive parameters of the impedance of an antenna-ground system vs frequency. Results from measurements on an attic antenna are given.

Schematic using a half wave rectifier Schematic using a full wave rectifier

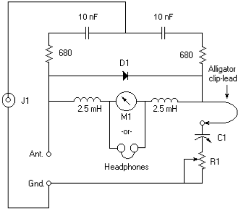

Fig. 1 - Ver. A of Antenna-ground measurement bridge.

The circuit in Fig. 1 was inspired by an Article in The Crystal Set Society Newsletter of Jan 1, 1995. It was written by Edward Richley. He used a 1 MHz crystal oscillator for his source, so had no problem with using a 200 uA meter. I use a sine wave function generator for my RF source, but a radio Service man's oscillator may also be used if it has enough output. Either of these sources cannot supply as much signal as the xtal oscillator, so I had to increase sensitivity. That's what the 2.5 mH chokes and 5 nF caps are for. The 2.5 mH chokes eliminate RF loading by any resistive component of the meter or phones on the diode detector. The 5 nF caps eliminate resistive DC loading on the detector from the two 680 ohm resistors. I lay out the components breadboard style on a nonconductive table to minimize stray capacity, keep connections short, and especially keep the signal source lead of J1 away from the connections to each end of D1. In my setup D1 is a 1N34A, M1 is a 0-20 uA DC meter, R1 is a 75 ohm non-inductive carbon pot and C1 is a two gang variable cap of 365 pF per section. I parallel the two sections when the antenna capacitance is above 365 pF. A lower sensitivity meter can be used than the one used here, at the cost of a requiring a higher applied signal to J1.

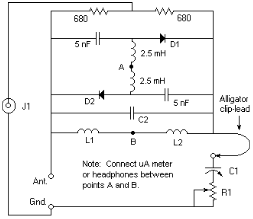

Fig. 2 - Ver. B of Antenna-ground measurement bridge.

If a sensitive enough meter is not available, a pair of high impedance phones (2000 ohms DC resistance) or preferably, a sound powered pair with the elements wired in series can be used. In this case, the generator must have its AM audio modulation turned on at its highest level. A modulation frequency of about 1 kHz is recommended. If the meter is used, do not connect the phones. If phones are used, do not connect a meter.

To use the bridge, tune the generator to a frequency of interest. Adjust C1 and R1 for minimum deflection on M1 or a null of the modulation tone in the phones. Increase the RF signal to J1 as much as possible in order to get the sharpest and most

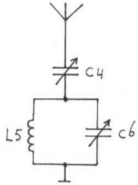
CALCULATING COMPONENT VALUES FOR AN ANTENNA TUNER

Dick Kleijer crystal-radio.eu
http://www.crystal-radio.eu/entunercalc.htm

In this article we are going to match a parallel LC circuit to an antenna.



Matching means, connecting LC circuit and antenna in such a way that there is maximum power transfer from antenna to LC circuit.
This article makes use of complex impedances, a explanation about this you can find here (external link).

There are several ways of matching the antenna to the LC circuit, I discuss here only the matching via a variable capacitor between antenna and LC circuit.

With the next calculator, the component values of this antenna tuner can be calculated.
Enter: frequency, value of the coil in the LC circuit (L5) and the unloaded Q of the LC circuit L5, C6
Also enter the complex impedance of the antenna, or the series component values of the antenna.
(when you enter both complex impedance, and series components, the complex impedance is used, and not the series components).
If you don't know the antenna impedance, use the standard values for the series components: 25 Ω, 20 µH en 200 pF.

Now with various settings of C1, the frequency range of the circuit, the voltage across coil L1, and the Q (across coil L1) are measured.

The measured voltages are Volt peak-peak.

The frequency range can be slightly influenced by the measuring amplifier which was connected across coil L1.

precise null. Measure the resistance of R1 with an ohmmeter. Use any desired method to measure C1. I use the cap. measurement range of my Fluke DVM. I'm sure the reader does not need to be reminded that this test involves radiating a weak RF signal from the antenna when making the measurements, so the length of time the generator is on should be kept as short as possible.

Possible issues: More sensitivity is needed or interference from antenna pickup of local stations obscures the bridge null.

If insufficient signal is available from the RF generator to provide satisfactory meter readings, one can use the more sensitive broadband circuit shown in Fig. 2. The values of L1 and L2 are 2.5 mH and C2 is set to zero in the broadband version. A full wave rectifier is used instead of the half wave one used in Fig.1 and it gives about twice the output. One can also change from using 1N34A diodes and try Schottky Zero Bias detector diodes such as the Agilent HSMS-2850 in either circuit. The HSMS-2855 Zero Bias diode is especially suitable for use in the circuit shown in Fig. 2 since it is a package having two independent diodes, one for D1 and the other for D2. One must be cautious when using the HSMS-2855 because the diodes can be damaged by the application of too strong a signal to J1. This can happen if the signal generator signal is very strong when the bridge is greatly unbalanced. It's best to start with a weak signal, balance the bridge, then increase the signal if necessary.

If the signal from the RF generator is not strong enough to override local pickup, thus obscuring the meter null, selectivity may be added to the bridge shown in Fig. 2 by making use of C2 and changing L1 and L2. If L1 and L2 are changed to, say, 10 uH inductors and C2 is made equal to 1200 pF, the bridge will be tuned to about 1 MHz. These changes will reduce the influence of local pickup upon measurement of antenna-ground impedance at 1 MHz. One suitable 10 uH inductor is Mouser's "Fastron" #434-23-100.

If one uses headphones instead of a meter as the null indicator, even greater sensitivity can be achieved by AF modulating the bridge signal generator and connecting a parallel L/C tuned to the modulating frequency of the generator across the phones. This will filter out much of the interfering cross talk from local pickup and pass the modulation tone with little loss. Suggested values are L=47 mH and C=0.5 uF if the modulating frequency used is about 1 kHz. A low cost coil having an inductance of 47 mH and a Q of about 9 at 1 kHz is available from Mouser as a Fastron Plugable Shielded coil, #434-02-473J ($1.20 each). Greater selectivity against cross-talk can be obtained by decreasing the inductance and increasing the capacitor.

I live about 9 miles from WOR and 12 from WABC, both 50 kW stations. 10 volts peak-to peak applied to the bridge overrides the local radio station pickup sufficiently to provide a clear null on the meter when using the circuit shown in Fig. 1 when using a 1N34A diode. A useable null with an applied signal of only 1.5 volts p-p can be obtained when using the circuit in Fig. 2 with zero bias detector diodes, sound-powered phones instead of a meter and the parallel LC filter.

Notes:

* If the RF source has too great a harmonic content, the bridge balance null will become less deep and sharp. That's why I used a sine wave function generator to assure a low harmonic content. If one uses a function generator for pure sine waves, make sure the symmetry control is set for best symmetry (minimum reading on the bridge microampmeter). In April

L12, only the outermost winding is removed to reduce inductance a little bit. This reduced the total wirelenght from 15 to 14.5 meters.

The frame of this antenna unit is made of 8mm polyethene sheet.

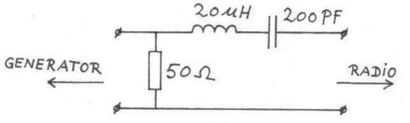
Tuning capacitor C2 is driven via a 1:5 vernier drive, so we can tune it very accurate. Tuning capacitor C1 has no vernier drive.

Experiments:

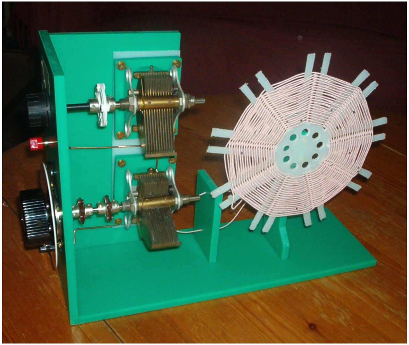
During the measurements the antenna unit is connected to the signalgenerator via a dummy antenna.

The dummy antenna.

Made with a resistor of 50 Ohm, a coil of 20 uH, and a capacitor of 200 pF. The 50 Ohm output resistance of the signal generator is in parallel with the 50 Ohm resistor.



The dummy antenna makes the receiver input is driven with a impedance of 25 Ohm in series with 20 uH in series with 200 pF.. This is about the impedance of a average longwire antenna. With the dummy antenna connected to the generator (but without the receiver connected), the output voltage of the generator is adjusted to 50 mV peak-peak.



The circuit L1,C2 has a high impedance (e.g. 1 M.Ohm). But the antenna has a low impedance (e.g. 10 Ohm), tuning capacitor C1 forms a impedance match between this high and low impedance.

With a certain value of C1, there wil be maximum power transfer from antenna to the circuit L1,C2. Then there is maximum voltage across the coil L1, and maximum sensitivity of the receiver. At low frequencies we must for instance adjust C1 to 100 pF, and at high frequencies to 20 pF, but these values are depending on the (lenght of) antenna we connect to it. For the circuit Q however, the lower the value of C1, the higher the Q. More information about this, you wil find here.

Coil L1 is wound with litzwire 660x 0.04mm (660/46 AWG), on a polypropylene former. This coil is described here as coil

2004 Tom Polk published a description and schematic for a low distortion medium wave home brew signal generator. It looks very good, and can be found at:
http://www.beecavewoods.com/testequipment/sinewave.html

* If the resistance of a specific antenna-ground system is greater than 100 ohms, use a pot of a higher value than 100 ohms.

* A typical antenna-ground system will show a capacitance of a few hundred pF at the low end of the BC band. Because of the series inductance in the system, the measured capacitance will rise at higher frequencies. At a high enough frequency the system will go into series resonance and the bridge will not be able to be balanced. To measure the system series resistance at or above this resonance, place a hi Q capacitor of, say 100 to 220 pF in series with the antenna. That will raise the resonant frequency sufficiently so that the capacitor-antenna-ground circuit will be capacitive, a null can be obtained and the resistive component determined. An NPO ceramic or mica cap should be OK.

* At my location, detected signals from local strong stations show up as fluctuations at about 15% of full scale on the meter, but are not strong enough to obscure the bridge nulls from of the signal generator's signal.

* Unless the signal generator connected to J1 is battery powered (most aren't), it is important to put a common-mode radio frequency choke in the power line to the generator. I made mine by bundling a length of 18 ga. lamp cord into an 18 turn coil having a 9 inch diameter, and then fitting a male AC plug on one end and a female socket on the other. The turns were kept together using twist ties.

What can one do with the measurement results?

The main practical thing one can do with the bridge is to Measure and Monitor antenna-ground circuit resistance. This resistance comes primarily from the physical ground, not the antenna and ground connecting leads or radiation resistance of the antenna. Any increase in the antenna-ground resistance serves to reduce the signal power available from the antenna. Any decrease, of course increases it. A halving of the antenna-ground system resistance provides a 3 dB increase in available signal power, if one properly rematches to the crystal radio set input circuit.

Measure: One can experiment with different grounds and various ground paralleling schemes to come up with the one that has the lowest resistance. Use of this one will result in maximizing the available signal power (more volume). Experiments using a counterpoise ground can be made.
Monitor: As has been recently been posted on the Yahoo Club: thecrystalsetradioclub, earth ground resistance deteriorates (increases) over time. This results in a gradual decrease in available signal power (less volume). Periodic measurement can alert one if this is happening so steps can be taken to correct the problem.

The other thing one can do, if one is mathematically engineering a crystal radio set, is to use the R and C values as parameters in the design. See Article #22.

Measurement results on an indoor attic antenna system:

My present external (as opposed to loop) antenna is in the attic. The horizontal element used to be made up of 7 twisted strands of #26 copper wire (17 ga.), suspended by strings about 1 1/2 feet below the peak of an asphalt shingled roof. It runs

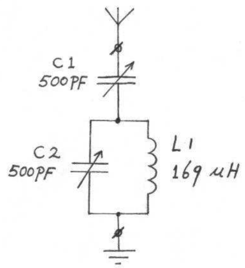
EXPERIMENTS WITH AN ANTENNA TUNER UNIT

Dick Kleijer crystal-radio.eu
http://www.crystal-radio.eu/enantunittest1.htm

Here some measurements done with my "antenna unit1".



Schematic of the antenna unit 1.

The antenna unit has a tuned circuit L1, C2.

If we only look at L1 and C2, then the tuning range is 550 - 2184 kHz. But if we also connect the antenna and earth, the frequency of the circuit will decrease, so we can also receive the lowest mediumwave frequency of 530 kHz.

Variable capacitor C1 and the antenna and earth are also a part of the tuned circuit, but the antenna and earth also give reduction of circuit Q.

along under the peak and parallel to it for 53 feet. The wire is about 24 feet above ground level. The lead-in, connected to the center of the horizontal wire, runs horizontally, at a right angles for about 9 feet and then drops down vertically to the crystal radio set location, about four feet above ground level. The ground system consists of a connection to the cold water supply in parallel with a connection to the hot water baseboard heating system. To achieve a low inductance ground connection I use 300 ohm TV twinlead, both conductors soldered in parallel, for each lead. The addition of a connection to the AC neutral does not seem to reduce the inductance or resistance of this antenna-ground system. I always suggest trying the addition of a connection to the AC neutral. Sometimes it helps.

The measured antenna-ground system capacitance was 295 pF at 0.5 MHz, 325 at 1.0 MHz, 410 at 1.5 MHz and and 660 at 2.0 MHz initially. The respective series resistances measured: 17, 12, 10 and 14 ohms. The equivalent reactance elements of this antenna are a capacitance of 285 pF in series with an inductance of 12.5 uH. Since my ground is composed of the house cold water supply pipes in parallel with the the hot water baseboard heating system pipes, much of the capacitance from the horizontal attic antenna wire is to them and the roof, not a real resistive earth ground. That, I think explains the low resistance and high capacitance readings. Probably the ground system is acting as a sort of counterpoise.

I decided to see if I could get greater signal pickup by changing to a very crude simulation of a flattop antenna. To do this, I paralleled the antenna wire with a piece of TV twinlead connected to it at each end and at the point of down-lead takeoff. The twinlead was separated from the 7/26 wire by about 2 1/2 feet. The new measured antenna-ground system parameters became: Capacitance: 430 pF at 0.5 MHz, 510 at

1.0 MHz and 860 at 1.5 MHz. The respective series resistance values became: 15, 12 and 11 ohms. The equivalent reactance elements became a capacitance of 405 pF in series with an inductance of 14.2 uH. Signal pickup increased by a negligible 0.8 dB at 710 kHz, and even that was, I'm sure, within experimental error.

One may want to compare these equivalent impedance components with the 'Standard Dummy Antenna', as specified in 1938 by the IRE (Institute of Radio Engineers) in 'Standards on Radio Receivers'. My reference for this is Terman's Radio Engineer's Handbook, first edition, 1943, pp 973 and 974. A rather complex equivalent circuit for the antenna is shown on page 974. It is stated that a simpler alternative network, given in footnote #2 on page 973, can be used when only the BC band is of interest. It consists of the series combination of a 200 pF capacitor, 25 ohm resistor and 20 uH inductor. Terman states that the two antenna equivalent circuits have closely the same impedance characteristics in the BC band. The impedance graph on page 974 and the impedance from the series combination of 200 pF, 25 ohm resistor and 20 uH differ, particularly in the resistive curve in the complex equivalent circuit. The 25 ohm resistance in the simplified circuit is probably taken from the resistance in the complex circuit, at the geometric center of the BC band. This resistance is shown as constant in the simplified circuit, and as a strong function of frequency in the more complex circuit. It is suggested that the complex equivalent circuit is theoretically derived, assuming a perfect ground and therefore does not include the resistance of the ground return path. The ground circuit can easily add 15-50 or more ohms to the circuit.

#20 Published: 11/24/01; Revised 04/16/2004

of -j14 ohms. The negative sign indicates a capacitor is needed. Here is the value for 1650 kHz:
XC=1/(2*pi*F*C)

Solving for C, we get:
C=1/(2*pi*F*XC)

C=1/(6.28*1650 kHz*14)
C=6,890 pf
This is a huge capacitor and would probably be a combination of fixed and variable capacitors.

Now, referring to the first antenna example before we added more capacitance, we can see what value of reactance is required to bring the antenna into resonance. Since that antenna had an impedance of 20 - j34 ohms, we would need a series inductor to combine with the capacitance of -j34 ohms. This inductance is:

XL= 2*pi*F*L

Solving for L we get: L=XL/(2*pi*F)

L=34/(6.28*1650 kHz) L=3.28 uH

These calculations were all done at the higher end of the broadcast band. When moving down to 530 kHz, the antennas we have been analyzing would have smaller resistance and higher negative reactance.

=-j241 ohms (capacitance has a minus sign)

The value of this complex impedance is:
= 20 + j207 - j241 ohms
= 20 - j34 ohms

As mentioned earlier the use of complex numbers allows us to simply add the resistance and reactance. The sign of the reactive component -j34 is negative and indicates the antenna is capacitive. It is also shorter than the resonant length (at resonance XL + XC = 0).

Now if you increase the capacitance of the antenna to ground with a flat top section, where the series capacitance increases to 500 pF, here is what happens:
XC=1/(2*pi*F*C)
=193 ohms
= -j193 ohms

The value of this new complex impedance is:
=20 + j207 - j193 ohms
=20 + j14 ohms

The sign of the reactive component is now positive, indicating the antenna is inductive, or long compared to resonance.

Use of the complex number notations also lets you figure what value of series reactance you would need to bring the antenna circuit into resonance. You could tune out the reactance and then match the remaining resistance to the input of the crystal set.

Referring to our last set of complex numbers: 20 + j14, you could bring the antenna circuit into resonance with a reactance

MEASUREMENTS ON RADIO RECEIVERS

35. Receiver Characteristics and Their Determination.[1]—Radio receivers are tested by employing an artificial signal from a standard signal generator to provide a voltage corresponding to that induced in the receiving antenna. This voltage is ordinarily applied to the receiver through a network, termed a dummy antenna, having characteristics such that the receiver views substantially the same impedance as it would in normal operation with an actual antenna. The receiver output is then observed by replacing the loud-speaker or telephone receivers by a suitable resistance load, with which is associated a power indicator.

The dummy antenna recommended for use in testing broadcast receivers is given in Fig. 78.[2] The impedance of this network in the frequency range 540 to 1,600 kc approximates that of the typical open-wire antenna resonant at about 2,500 kc, and having a capacity of the order of 200 μμf. At higher frequencies the network approaches a constant impedance of 400 ohms, and so resembles a nonresonant transmission line of corresponding impedance.

[2] Where tests are to be made only in the standard broadcast frequency range, an alternative network consisting of a capacity of 200 μμf, resistance of 25 ohms, and an inductance of 20 μh, all connected in series, is commonly used. Such a dummy antenna has practically the same impedance as the recommended network in this frequency range.

FIG. 78.—Standard dummy antenna used for testing broadcast receivers, together with its impedance characteristic.

Working With Antenna Impedance

Jack Bryant
Birmingham Crystal Radio Group
http://www.crystalradio.us/antennas/impedance.htm

This is an elaboration of a post I made on the Rap 'N Tap Discussion group. The objective was to explain how a multi-wire flat top antenna adds capacitance to the antenna, while making it more inductive. This is an exercise in complex numbers. For example the expression 20 + j40 displays 20 ohms resistance and 40 ohms of inductive reactance. The complex number approach allows us to simply add series resistance, capacitance and inductance. The resistance remains constant when the frequency changes. However, the reactance of an inductor increases with frequency. The reactance of a capacitor decreases with frequency.

For purposes of illustration, assume an antenna with the following parameters for R, L and C in series for F=1650 kHz (our frequency of interest):

Rtotal = 20 ohms (total of radiation resistance and losses, including ground losses, since we are using a Marconi type antenna, i.e., worked against ground.)

L = 20 uh; the reactance is calculated as:
XL= 2*pi*F*L (where 2*pi =6.28, F is in hertz, and L in henries)
=207 ohms
=+j207 ohms(inductance has a plus sign)

C = 400 pF; the reactance is calculated as:
Xc=1/(2*pi*F*C) (Where F is in hertz and C in farads)
=241 ohms

ANTENNA MATCHING

by Kenneth A. Kuhn

www.kennethkuhn.com/students/crystal_radios/antenna_matching.pdf

As discussed in an earlier chapter the ten to thirty meter antenna used for crystal radios has a very low resistance and a high capacitive reactance. The ground resistance discussed previously is typically in the several tens of ohms and is effectively in series with the antenna. As an example, an antenna/ground system may have an impedance of 20 –j1000 ohms at 1 MHz. For maximum power transfer from the antenna to the resonant circuit the input impedance of the set should be a conjugate match –that is have similar resistance but the reactance will be equal in magnitude but opposite in sign. For the example this means that the crystal set should have an input resistance of about 20 ohms and a reactance of about +j1000 ohms (160 uH) at 1 MHz. The positive reactance is obtained by an inductance in series with the antenna circuit. This inductance should be variable to tune out the capacitive reactance of the antenna across the AM broadcast band. Tuning is not sharp as the Q of resonance is low. Table 1 shows some typical values. Note that the inductance tuning range becomes wider for longer antennas since the capacitive reactance drops rapidly as the length approaches one-quarter wavelength at the upper end of the AM band. It is important that this series inductance have very low losses or the advantage of using it will vanish –a lossy inductor could be worse than nothing.

Antenna Length	Typical Antenna XC @ 550 kHz	Typical Antenna XC @ 1.7 MHz	Antenna series Inductor tuning range
10 m -	j4040 ohms -	j1250 ohms	1200 –120 uH
15 -	j2680 -	j780	780 – 70
20 -	j1990 -	j530	580 – 50
25 -	j1580 -	j360	460 – 30
30 -	j1290 -	j240	370 – 20

Table 1: Antenna series inductance tuning range

One effect of not tuning out the reactance of the antenna is that the resonant frequency of the tuned circuit will shift because the antenna becomes a reactive load. One way to know if the series inductance has been tuned to the right value is that the station is received at the calibration point –assuming the radio tuning was calibrated.

The next issue is creating a low input impedance of several tens of ohms. There are two ways to do this and they are essentially the same. One method is wind a turn or so of wire near the ground end of the coil of resonant circuit –one end of the wire goes to the series inductor to the antenna and the other end connects to ground. This small winding transforms the low antenna/ground impedance to a high impedance across the coil. The other method is to make a tap a turn or so above the ground end of the coil of the resonant circuit to accomplish the same effect. If the winding or tap is too few turns then there is an impedance mismatch and a weak signal will result although selectivity will be relatively sharp. If the winding or tap has too many turns then the coil is overloaded by the antenna/ground impedance which also results in weak signals and the selectivity will be broad. The optimum is the point of proper impedance match although it is not very critical. The issue is how to determine the proper point. A second issue is that the required impedance level varies across the AM broadcast band. Thus, the tap should be variable.

If the coil is wound on a ferrite toroid core which enables a high degree of flux coupling from turn to turn then it is fairly easy to calculate at what turn a tap should be for the desired impedance transformation. However, our coil is typically an air-core solenoid which has a complicated flux relationship. Calculation is difficult and very error prone. The best way is to make a variety of taps and measure the impedance using laboratory methods and note the results. I will present the data of just such an experiment on a typical coil for crystal radios when this article continues …

NOTES:

Introduction

This handbook is primarily devoted to radio wave propagation. This is not a topic specific to crystal radio but to radio generally and here with a mind to LW/MW propagation. For many in the crystal radio hobby, long-distance reception, or DX, is an interesting and sought after goal. Understanding propagation adds to the joy of the hunt. Additionally, as crystal sets have no amplification or signal modification other than rectification, they are more subject to the vagaries of atmospherics and propagation irregularities.

We open with Tom Giella's excellent layman's overview of MF propagation. This discussion reviews medium frequency propagation from a thoroughly modern standpoint, benefitting from land and space-based tools and 100 years of progress in understanding the phenomenon. This is the answer and if propagation is your only interest then you can stop reading after this article. Following this we step back in time to the days of spark transmission and unamplified reception. First Chen-Pang Yang reviews the intellectual background of the scientists and engineers who were involved and the new observations they were working to explain. From here I provide source documents written by the players themselves. These give a feel for the excitement of discovery and advancement that characterize the early days of radio. Finally, I provide a personal study on propagation made in the late 1980's. This gives some personal perspective as well as highlights the interesting kind of projects available to the hobbyist.

Of general note, the web is a marvelous source of data and information. Many long-time crystal set builders, and many others have created dedicated sites to disseminate information and resources, to share their creations and knowledge. I am eternally in your debt. All of the material in this handbook is copyright for which I have not sought permission. Therefore this is not presented for publication or copy. It is only my personal resource. I encourage anyone finding this copy to pursue ON THE WEB the web pages identified within. I include the name of the author and web address of each section. I wish to sincerely thank every author presented for their excellent pages and ask forgiveness for my editing into this handbook.

Joseph J. Carr

Postscript 2010

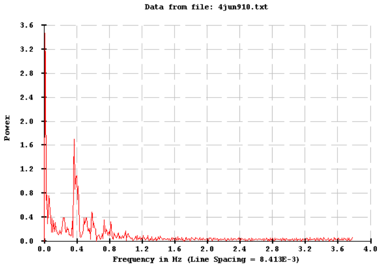
The above report describes a study I made back in 1987 – 1991. At the time my tools included a good communications receiver (Yaesu 7700) coupled to a Commodore 64 computer. The connection was cobbled together via the game port interface. Looking back, it seems amazing that it worked at all. Today with modern receivers like my Icom R75 we can connect directly to a modern personal computer with the radio's built-in interface. Monitoring several bands becomes an easy pursuit with the correct software.

Below I provide two figures made with my current setup. The date 18 October. The record shows simultaneous monitors on 2.5, 5.0, 10.0, 15.0, and 20.0 MHz WWV. The easiest bands to interpret are for 10 and 15 MHz. For 2.5 and 5 Mhz the record is best interpreted in terms of D-layer absorption. 20 MHz is barely reached except for two small blips at 16 and 17h CST.

small compared to the 15MHz carrier. On top of that is a second interesting beat in the amplitude with 40 to 50 second period or about 0.02Hz (also seen on the power spectrum).

Voila! No noise at all, just signal everywhere.

Supplemental Records



Power spectrum of the data collected on 04 June, 1998. The data was converted to the frequency domain via a Fourier transform.

MEDIUM FREQUENCY RADIO WAVE PROPAGATION THEORY NOTES

Layman Level Explanations Of "Seemingly" Mysterious MF Radio Wave Propagation Occurrences

By: Thomas F. Giella, W4HM

http://www.wcflunatall.com/propagation5.htm

0.) Introduction.

Welcome to the "W4HM Medium Frequency Radio Propagation Theory Notes" weblog styled website. Contained within you will find the most comprehensive explanation of medium frequency radio propagation occurrences on the Internet.

In my personal opinion understanding and taking advantage of low/medium/high frequency radio propagation conditions is an integral part of successful DX operation. Therefore this site exists as an educational tool.

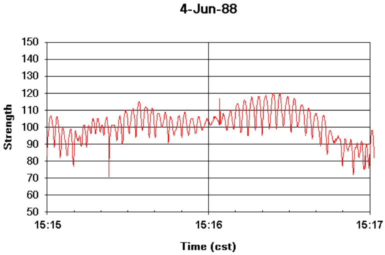
This website is permanently under construction as I add new data and research information continuously. If you see any spelling or sentence structure errors I've overlooked "please" feel free to advise me, thanks! Also feel free to ask for inclusion on this website of "legitimate" propagation theory. Remember that the definition of "theory" means that the concept has not or can not be definitively proven in a laboratory setting but can be inferred via systematic study.

These theory notes are primarily applicable to the 300-529 kc long wave aviation and marine navigation beacon band, 600 meter band, 530-1700 kc AM broadcast band, 160 meter amateur band and 120 meter shortwave tropical broadcast band. However much of the content is also applicable to the 3000-30000 kc HF shortwave spectrum.

A while back I became involved in a propagation research project of sorts on 10, 6 and 2 meters. I have set up a propagation beacon currently on 10 meters, the frequency is 28131 kc USB +1500 Hz using 25 watts. Actually there is a group of hams running the propagation beacons in the U.S. and around the world. Basically it's a marriage between digital PSK31 and APRS technology, actually software's run on a computer that is interfaced to a transceiver. Beacon transmission will commence on other HF bands in the future, with the ultimate aim of all HF bands and even 160 meters. It's been very interesting so far watching Es and F2 propagation openings on 10 meters, when conventional propagation wisdom says that the opening should not be occurring. A knowledgeable observer can also pick out Sporadic-E (Es) openings. You can learn more about the concept by clicking here for HF PropNET.

I have attempted to keep the propagation theory explanations in simple to understand layman terms, because long complicated technical explanations can be boring and make one's eyes glaze over. Unfortunately though sometimes while trying to keep things simple, certain definitions, meanings and technical aspects can get watered down or even lost, which tends to open me up to criticism from certain fellow space weather scientists that just don't understand the educational and public relations concept of the keep it simple stupid (KISS) principle. I choose to use W6SAI's (SK) "KISS" method of writing and communicating. I have found that this method works best whether it be in teaching about space or atmospheric weather or any other subject.

seen the characteristic signature of signal fading. There are in fact two periods of fading superimposed, one of about 50 seconds, the second about 5 seconds. The fading has the typical rounded crests and sharp drop to the separating nodes. This pattern results from the beat amplitude of two or more interfering signal frequencies.

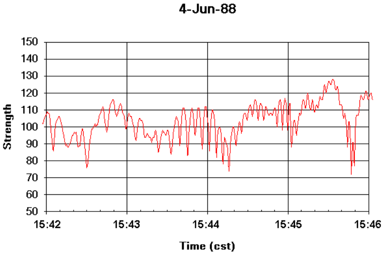


characteristic signature of signal fading

The second chart is from a run of only seven minutes giving about a tenth second interval between readings. There the fading signature shows with about 50 beats over the two-minute interval shown. Fading generally results from the interference of the same signal arriving from two paths at the receiver. A power spectrum of the data shows a strong peak around 0.4 hertz corresponding to the dominant beat (25b/m or 0.4b/s). For a beat to be set up the signals traveling along separate paths, (presumably a single hop and a double hop) they must not merely be arriving slightly out of phase but also with a difference in frequency of 0.4Hz. That shift is extremely

The "Grass", Noise Revealed

Some final words and observations concerning the "grass", the noise on the records with the very high frequency. Hidden within that noise lies some interesting signals and an interesting message. This "noise" seen on the records is in fact just more signal, but at a higher frequency than I have been presenting. The following charts were made on 04 June, 1988. They were taken specifically to look at the high frequency content of the signal. It should be noted that in both charts the signal strength scale remains exactly the same as in all the previous charts so the amplitude of the "noise", the range from crest to node is quite significant when compared to the daily variations being measured.



characteristic signature of signal fading

In the above case I gathered a standard 3200 points over 29 minutes with no filter giving a half-second period between points. The chart shows four minutes of data and on it can be

We hams are a curious lot with inquiring minds. A good number of us have a keen interest in low, medium, high and very high frequency radio wave propagation mechanisms and this website conglomeration is directed at this forward looking group.

We also have a segment in our radio service that is basically disinterested in radio propagation and don't feel it necessary to understand it in order to successfully work DX, which is certainly okay. However within this group exists a total lack of understanding concerning the most basic aspects of the subject. Often times I will hear them say, "The band is shifting". This lack of basic knowledge can be traced back to the licensing process where very few questions exist in the exam pools.

Then we have a third and smaller group with gigantic runaway egos that insist that they are omniscient by virtue of their Extra Class license, ARRL DXCC entity totals and "possible" electrical engineering backgrounds. Anal Retentive types?! They spend their time arguing with ignorance (Alchemists) against explanations put forth via this and other scientists, with solid backgrounds in atmospheric and/or space weather physics. You know who you are and should be ashamed of yourselves.

1.) Medium Frequency Radio Wave Propagation Overview-

Popular Myth- We don't understand medium frequency radio wave propagation mechanisms and therefore it can't be forecasted.

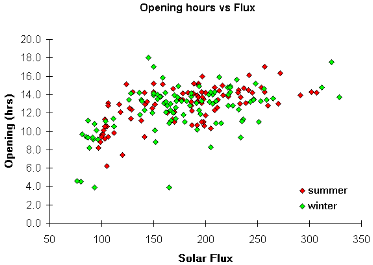
Fact- Yes it can and is on a regular basis at W4HM MF/HF/6M Frequency Radio wave Propagation Forecast http://www.solarcycle24.org and MF at http://www.wcflunatall.com/propagation.htm .

a.) Medium frequencies encompass 300 to 3000 kc. The simplest way to look at medium frequencies with respect to propagation issues from a layman's point of view, is to accept the fact that propagation is poor the majority of the time (See definition #6. Electron Gyro Frequency Absorption), especially past approximately 1250 miles (one refraction off of the E layer), with occasional short-lived good periods as far as 3200 miles.

Medium frequency radio waves possess elliptical polarization, with the signal splitting into ordinary and extra-ordinary rays. These rays can propagate in or out of phase, more often out of phase. The out of phase extra-ordinary ray represents a 50% power loss on the receive end of a path.

b.) Why is medium frequency propagation poor the majority of the time? D layer absorption! At daytime the D layer which is at an approximate height of 30-60 miles in the mesosphere, totally absorbs medium frequency RF signals the majority of the time. I say the majority of the time because at higher latitudes, during the winter season and especially at the low part of a sunspot cycle, daytime penetration of RF signals through the weakened D layer and then refraction via the E layer and/or Sporadic E (Es) clouds does occur. Another issue is the fact that the D layer does not totally disappear at night. Many books that deal with wave propagation erroneously state that the D and E layer's disappear after sunset, totally incorrect thanks to Galactic X-Rays, Galactic Cosmic Rays and Lightning.

otherwise. Increased ionization levels increase the signal absorption as well. Also, times of high solar activity bring instabilities in the earth's geomagnetic field. Both of these effects have an important impact on signal strength.

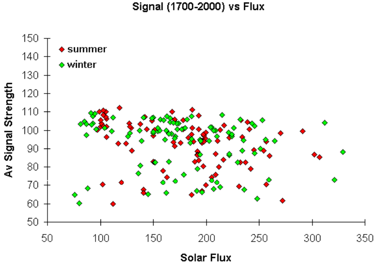


Solar activity (flux) vs length of openings

Solar activity (flux) on the other hand does indeed improve the conditions in terms of the length of the openings, especially for levels of flux above about 120. This is logical when considering the overall increased ionization levels. While the increased ionization may actually hurt signals by increasing absorption and causing greater geomagnetic instability, it does make for longer openings. Next: The "grass", noise revealed..

Signal Strength by Solar Activity

The following charts show the relationship of solar flux to signal strength and to the length of time for an opening for propagation along a circuit. Color coding provides an indication of the variation due to season as seen in the previous section. In this case I have distinguished "summer" from "winter" data on these charts in the following way: Winter = October to March, Summer = April to September.



Plot of signal strength averaged over the midday period 1700 - 2000UT

Plot of signal strength averaged over the midday period 1700 - 2000UT (11-13 CST).
For both summer and winter seasons I see a weak but real inverse relationship of decreasing average signal strength with increasing solar flux. It has often been stated that propagation improves during times of high solar activity, this data suggests

c.) Background electromagnetic radiation in the 1 to 10 Angstrom range (Hard X-Rays) is a major source of ionization of the day time D layer, with our Sun as the source of Cosmic Rays, also playing a role.

The following information was contributed by Carl Luetzelschwab K9LA, a scientist and all around great guy with a very good understanding of radio wave propagation.

.....A couple years ago I was playing with Proplab Pro on a one-hop 936km path on 160m during daylight. I plotted absorption versus sunspot number. I expected a nice monotonic increase as the sunspot number increased. But the plot showed that absorption started at about 60dB at zero sunspots and was constant out to a sunspot number of about 50. Then it started climbing, reaching 100dB at a sunspot number of 150. This suggested that there was something other than hard X-rays and Galactic Cosmic Rays as the source of daytime D region absorption. So I dug into Davies 1990 (page 61), Hunsucker and Hargreaves (page 31), and Brekke (page 233). They all seem to point to the Lyman-alpha line of the solar spectrum at 1215 Angstroms ionizing NO as the main source of the quiet daytime D region. So in terms of my absorption versus sunspot number plot, the flat portion up to a sunspot number of 50 is probably due to the Lyman-alpha line ionizing NO. Then above a sunspot number of 50 the hard X-rays start contributing as the Sun becomes more active.....

Carl has produced two really good .pdf files on 160 meter propagation in 2003 and 2004. Read them here: 160 Meter Propagation & Disturbances To Propagation . He also has a propagation website with allot of good information on it at K9LA's Amateur Radio Propagation. In 2009 Carl produced yet another excellent article on 160 meter operation at Is This

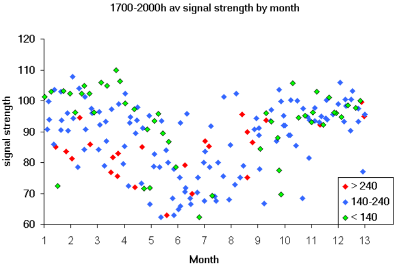
opening hours versus season

When plotting the length of time of the openings by season the situation is reversed with longer openings showing a weak but real preference to the summer season. This results principally from the longer time of ionizing radiation on the ionosphere, but in this case moderate to high levels of solar flux can add one to two hours of additional opening per day. I agree with the oft-stated general conclusion that winter is the best time for long distance communication by HF radio, but given the scatter I would temper that by addressing more closely the question of solar activity. Next: Signal strength by solar activity..



signal strength versus season

This chart, already presented in section 3.2, clearly shows that the summer season does not provide the same signal strength that can be found in winter. In general summer openings have low signal strength and greater variation from day to day. Overall they are less dependable. The chart distinguishes data collected under conditions of different levels of solar flux, (low flux in green to high flux in red). Curiously, there is a clear association between the strongest signals and the lowest levels of solar flux.

Ionosphere Profile

Also speaking of the ionosphere at and near solar minimum the mid and high latitude D layer of the ionosphere at mesosphere altitude cools approximately 2 degrees C, contracts in thickness and signal absorption in the layer increases.

While I'm visiting the subject of electromagnetic radiation, our Sun emits electromagnetic radiation and matter, as a result of the nuclear fusion process. Electromagnetic radiation at wavelengths of 100 to 1000 Angstroms (Ultraviolet) ionizes the F layer, radiation at 10 to 100 Angstroms (Soft X-rays), as well as Galactic Cosmic Rays ionize the E layer. Galactic X-rays, Galactic Cosmic Rays and Lightning are the reason that the E layer is "always" present at night time, the D layer also. Background electromagnetic radiation in the 1 to 10 Angstrom range (Hard X-Rays) is a major source of ionization of the day time D layer,

Via K7RA's weekly ARRL Propagation Forecast Bulletin #46 published on November 9, 2007:

In last week's bulletin, Carl Luetzelschwab K9LA said the closest measurement we have to radiation that ionizes the F2 region is the GOES X-ray data at 0.1 to 0.8 nm. K9LA says that is not correct- he received an e-mail from Michael Keane, K1MK, with the following information:

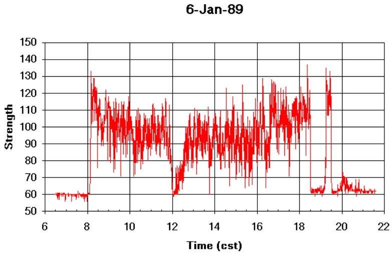
"There does exist an instrument that measures solar EUV flux directly. That is the SOHO Solar EUV Monitor (SEM) at http://umtof.umd.edu/semflux. One SEM channel covers solar EUV in the 17-70 nm range. The other channel monitors just the 30.4 nm resonance line of singly ionized helium. In most models, this 30.4 nm line by itself represents 25-50% of the energy input to the thermosphere/ionosphere."

Galactic Cosmic Rays are not rays at all, but particles. They are ionized atoms, atoms with missing electrons ranging from a single proton up to an iron nucleus and beyond but typically protons and alpha particles, which have 2 protons and 2 neutrons. They originate from deep space, being produced by a number of different sources, such as other stars, and more exotic objects, such as supernova, which are exploding stars and their remnants, neutron stars, black holes, and distant galaxies. Cosmic Ray particles travel very close to the speed of light, and are highly energetic.

Signal Strength by Season

After spending some four years collecting and analyzing propagation data, it is reasonable to have a few observations concerning the subject. I have often read general statements concerning propagation versus time of year and solar cycle, so how did this study compare? Keep in mind that the entire data set is from a single circuit, Ft. Collins, Colorado to Houston, Texas, and that it is for a single frequency, 15.000 MHz. While it cannot be generalized to all HF radio, it provides a good test under semi-controlled conditions. Another assumption that is implicit in all this data is that the transmitted power remained constant over the whole period. I will make that assumption while noting that I did not ever confirm it to be true.

The following charts addresses the question of signal strength and opening hours versus season. Color coding provides an indication of the variation due to solar flux, but this will be explored more in the next section.



06jan89
Major flare at 1805UT, (1205 CST). Also note the evening signal dropout and return.

While on the subject of distant galactic objects, on 12/27/2004 more than a dozen spacecraft recorded the brightest event from outside the solar system ever observed in the history of astronomy. This gamma and x-ray producing super flare was emitted by a Magnetar star named SGR 1806–20. This star is an estimated 50,000 light years distant in the constellation Sagittarius on the far side of the Milky Way galaxy and obscured behind dense interstellar clouds. A similar event also occurred in 1998.

Upon arrival at Earth the X-rays were powerful enough to increase absorption in the D layer of our ionosphere and create a dayside Sudden Ionosphere Disturbance (SID) and a blackout of radio signals, amazing!!! To read more about this rare event check out this link at: http://skyandtelescope.com/news/article_1464_1.asp and http://www.sciencedaily.com/releases/2006/02/060221084628.htm .

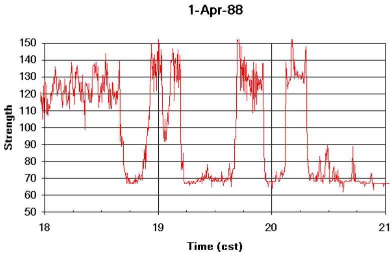
d.) Recently I saw a post on the Topband Reflector lamenting the seemingly unexplainable differences in 160 propagation on certain paths from night-to-night. is there a reasonable explanation? Yes, unfortunately small increases in the density of the night time D layer over short periods of time, caused by smaller solar flares and also the general variability of the solar background X-Ray flux level of greater than A0, can have a profound negative impact on propagation in the form of increased absorption of high and even mid latitude medium frequency signal paths, both on the medium frequency AM broadcast band, 160 and 120 meters. Why? It only takes 10 electron volts (ev) of energy to ionize the atmosphere and 1-10 Angstrom x-ray photons energize the atmosphere at a factor of 100. This translates into D layer absorption of medium frequency signals. The lower half of the medium frequency broadcast is always affected first followed by the upper half of the medium frequency AM broadcast band, then 160 and 120 meters. If you learn nothing else on this website, remember this simple explanation and pass the word.

e.) After much personal observational research over a 35 year period, I've come to the conclusion that high and mid latitude TA and TP propagation paths tend to open up only after an approximate three day period of time passes with an energetic proton event of no greater then (10+0) on the medium frequency AM broadcast band, 160 and 120 meters.

f.) Also there are daily extremes of the background x-ray flux level. So even though the daily average might have been pretty good at say A1.1, the daily "extreme" maximum could have been C1.5, which would have been bad and would have caused a short period of increased D layer absorption.

g.) Though high latitude paths on the day light side of the Earth are primarily effected, night time high latitude paths can also be impacted by higher intensity energetic proton events. This fact is still stubbornly opposed by some otherwise very knowledgeable space weather physicists hung up on high latitude threshold Riometer data tied to Polar Cap Absorption (PCA).

h.) Another wrench in the gears preventing consistent good propagation on medium frequencies is related to Sporadic-D (Ds) absorption. Sporadic-D (Ds) occurrences have an interrelationship with brief but intense Sun based and Galactic Cosmic Rays, extremely large positive cloud to ground lightning strokes and interrelated Elves. Very large bursts of Gamma Rays have also been observed to occur in conjunction with Sprites.



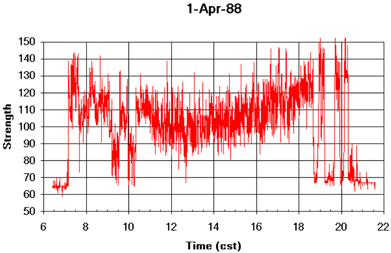
record for 01 April, 1988, detail

The above view focuses in on 18 to 21 CST showing more detail in the features. They clearly represent moments where the ionosphere electron density is passing repeatedly through the critical density for propagation. These features show a sinusoidal variation in electron density with a period between 25 and 30 minutes, (from drop to drop). I interpret the variations as density waves propagating in the ionosphere. A test of this would require one or preferable two other beacons being monitored at a close frequency to see whether the same features appear offset in time. Note also on the first chart that there are two signal loss periods between 9 and 11 CST as well, more evidence of unsettled conditions in the F layer that day.

Similar features appear on other records already presented in this article such as 06 January, 1989.

Density Waves

On a number of records I found interesting features which were not easily explainable. The record below for 01 April, 1988 shows a series of falls and jumps in signal strength between 18 and 21 CST. Similar features can occur on the morning side as well as the evening side, but seldom near midday.



record for 01 April, 1988

i.) Also there is another unavoidable problem, Magneto Ionic Power Coupling. Antenna polarization plays a large role in the success of a long haul DX contact. As a medium frequency RF signal traverses Earth's magnetic lines of force in a perpendicular manner on high and mid latitude paths say between W3 land and SM, higher angle horizontally polarized signals are more readily absorbed than lower angle vertically polarized signals. On other propagation paths on the globe opposite results can be found, i.e., horizontally polarized signals suffer less absorption on a propagation path between VK6 and W6 or S9 and W4.

Magneto Ionic Power Coupling expert NM7M Robert Brown, PhD. has a good educational thread on this bugaboo on the May 2002 Topband Reflector. The thread can read in its entirety by going to this link Topband Reflector May 2002 Archives Layer .

Also an excellent but more technically oriented website covering 160 meter propagation and more is the "HF Propagation Tutorial" by NM7M Bob Brown, Ph.D. and hosted by ON4SKY Thierry Lombry and can be found at: http://www.astrosurf.com/luxorion/qsl-hf-tutorial-nm7m.htm

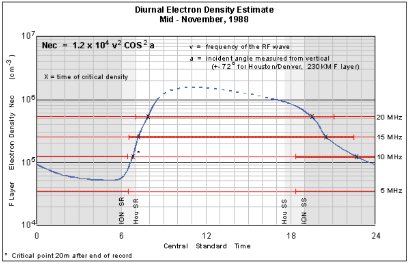
Electron density versus altitude as per section 2.2. This chart shows lines of criticality for different transmission frequencies on the Houston - Ft. Collins circuit. As the ionosphere ionizes in the morning or recombines in the evening, the density passes critical in the altitude range of 220 to 250 Km. Note that the F-Layer density never falls below critical for 5MHz, but does affect 10 through 20MHz. The November 1988 test was somewhere between solar minimum and maximum. (from Tascione, 1988)



curve of the diurnal change in ionosphere density

The plot shows that the ionosphere goes through a morning period of fairly rapid ionization peaking perhaps around 10am CST (1600UT). Then the process stops and reverses, going through a slower recombination period in the evening and into the night until near ionosphere sunrise the process again reverses and repeats the rapid ionization. This plot in fact compares quite well to published mid-latitude ionosonde data such as Olivier and others, 1988. It is even possible, where circumstances permit, to see more rapid ionospheric variations as described in the following section. Next: Density waves..

Earth's Geomagnetic Field

Poor Man's Ionosonde

My reading suggested a solution to the ionization problem described in the previous section. This solution dispensed with the notion that the jump in signal strength was caused by some jump in F layer ionization. It can be found in the relationship between the main parameters affecting propagation: Nec - electron density (cm^-3), v - frequency, and a - incident angle measured from vertical. The expression is as follows:

Nec = 1.2 x 10^4 v^2 cos^2 a

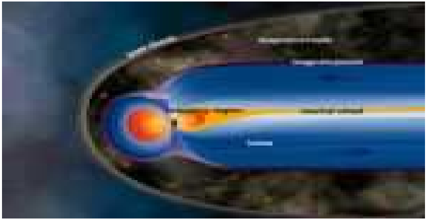
If this expression were true, then it was simple to devise a test to confirm it. If the ionization truly proceeded at a much slower rate, it should affect different radio frequencies at different times, in a regular manner. The beacon, WWV, transmits as previously stated at several frequencies, 2.5, 5.0, 10.0, 15.0, and 20.0 MHz. With this beacon, I could maintain the same basic circuit geometry. In mid November, 1988 I conducted a series of recordings at 5.0, 10.0, 15.0, and 20.0 MHz which, when plugged into the above expression gave me discreet electron densities.

F Elev	Angle a	Frequency			
		5 MHz	10 MHz	15 MHz	20 MHz
250	71	3.34+E4			
240	71		1.24+E5		
230	72			2.59+E5	
220	73				4.26+E5

The signal jump would give me the exact time that the F layer passed the calculated critical density. The following chart is my curve of the diurnal change in density, a sort of "Poor-man's" ionosonde.

electron density, radio frequency, and incident angle which I explained in section 2.3. The answer to the problem presented itself quite simply: My circuit, Ft. Collins to Houston had a fairly fixed geometry (if you assume a constant 230 Km height for the refracting region, close but clearly not constant), and a single radio frequency of 15 MHz. The only variable then is the F layer density which goes critical at about 2.6 x 10^5 cm^-3. Below that density there can be no propagation. As the F layer ionizes, quite slowly perhaps, it passes that critical density and causes the sudden jump in strength seen on my records.

Pretty neat.. If you gather data and think about a thing, you are bound to learn something fascinating. The above relationship quickly suggested to me the experiment described in the following section.



Earth's Magnetosphere

j.) Geological effects such as earthquakes and volcanic eruptions, as well as meteorological effects such as troposphere originating Internal Buoyancy/Gravity Waves (IBGW), stratospheric level Quasi-Biennial Oscillations (QBO) and stratospheric warming (See definition #20 on Stratospheric Warming) have a negative effect on medium frequency RF signals in the form of small to medium increased absorption variations of medium frequency RF signals via the D layer caused by traveling ionosphere disturbances (TID's). Also temperature and moisture discontinuities (frontal inversions) can refract/scatter medium frequency radio signals in unpredictable ways, most notably on high transmitted RF power levels.

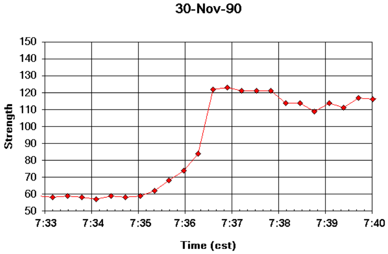
k.) The Quasi-Biennial Oscillation (QBO) is a wind shift in the equatorial stratosphere, an oscillation from easterly to westerly and back on the time scale of approximately two years (26 months) and is a source of Internal Buoyancy/Gravity Waves (IBGW's) which create absorptive perturbations in the D and E layers.

l.) A note, the E-valley/F layer ducting propagation mechanism does not exist only during gray line periods. Internal Buoyancy/Gravity Waves (IBGW's) are a source of the ducting mechanism and allow for occurrences of ducting along any propagation path in total darkness. Measurement of the timing of arrival of propagated medium frequency RF signals demonstrates the existence of the ducting mechanism, versus conventional numerous E layer land/ocean surface hops which, would allow for approximately 40 db of attenuation on a North America to Europe propagation path.

Another note! When it comes to 160 meter vertical antenna's you can get a lower take off angle (TOA) from a full 1/4 wave vertical or electrical 1/4 wave tee vertical of 10-20 deg., versus ~30 deg. with the inverted L. However it's a moot point as the night time E layer MUF blocks 160 meter low angle transmitted radio signals from ever reaching the F layer to be propagated. So unlike with high frequency propagation, medium frequency propagation success does not require the lowest of take off angles.

Also higher take off angles of 30-40 deg. via the inverted L are better able to take advantage of the low signal loss E valley-F layer propagation duct mechanism, a form of Chordal Hop propagation.

A solar flux of at least 150 is necessary for routine stable formation of the E Valley/F Layer ducting mechanism. Therefore formation of the duct is less prevalent at the bottom of solar cycle and long haul propagation poorer at solar minimum.



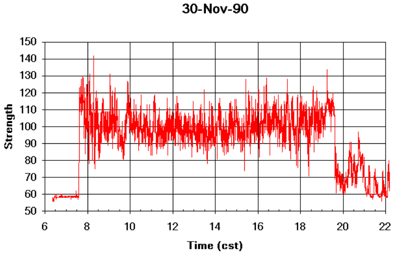
Record for 30 November 1990, detail

At the time I had the idea that the rise in signal strength in the morning, (and drop in the evening) was associated directly with the ionization of the reflecting F layer. As the layer ionized under the rising sun the signal would pick up. The records though could not be interpreted in that manner. As I thought about it, I realized that there were two problems with my theory: First, I noted the curious fact that sunrise on the F layer, and therefore ionization, took place up to one or two hours prior to the morning jump in signal strength (and vise versa in the evening). If the rise in strength was caused by a rise in ionization, why didn't it occur earlier? Secondly, the duration of the jump, sometimes in just seconds was far too rapid. The volume of refracting space in the ionosphere was simply too large to be illuminated by sunrise and ionize so rapidly.

Thinking about this problem sent me to the textbooks and literature. There I learned about the relationship between the

Ionization Problem

Early on in my project I encountered a problem in the interpretation of the data. Most records like the one below for 30 November 1990, showed a very rapid increase in signal strength from near 60 (S0, no reception) to a maximum of 120 or more (S9+, extremely strong).



Record for 30 November 1990

The time from nothing to maximum was often under a minute or two, as shown in the detail chart below where in the minute around 7:36 am CST the signal makes its jump. (This also shows some of the tight detail available on the records which looks spiky on the normal 15-hour presentation charts).

m.) Yet another mechanism to deal with that impacts medium frequency radio wave propagation in a negative fashion is the D Layer Mid Winter Anomaly. It is a period of increased medium frequency radio wave absorption at high and mid latitudes occurring in mid winter and is associated with sudden stratospheric warming and the Quasi Biennial Oscillation (QBO).

n.) The HAARP ionosphere research program, earthquakes, volcanic eruptions, thunderstorms, lightning (especially positive cloud to ground strokes), elves, tornadoes, hurricanes and even man made activities such as rocket launches including the space shuttle, are all sources of (IBGW's). Many times I've heard ham's lament that propagation was going to go to crap due to another space shuttle launch, in a sense they are correct.

o.) Another issue facing medium frequency AM broadcast Band DXers and 160 meter operators is lower latitude propagation path absorption due to the Equatorial Ring Current. This phenomenon acts as a repository for precipitated electrons and the end result is unpredictable medium frequency RF signal blockage absorption and refraction. Absorption is similar to higher latitude Aurora absorption.

p.) LF propagation theory is out of my realm from a standpoint of formal education. Alan Melia G3YNK is studying LF propagation and has made some very interesting observations and put forth some fascinating theories.

Here are some interesting website links concerning LF and ELF radio propagation theory.

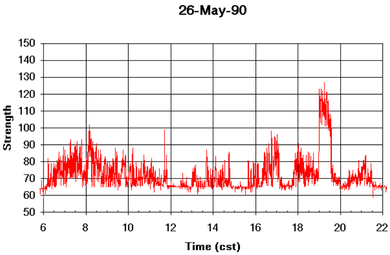
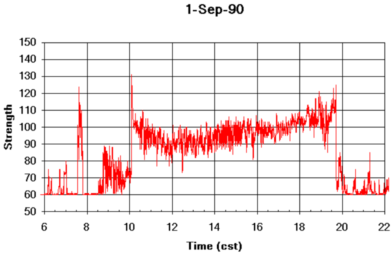
2.) Aurora Oval Blockage, Absorption And Refraction-

The aurora ovals "generally" have a negative impact on medium frequency propagation. If the path over which you are communicating lies along or inside one of the Aurora Ovals, you will experience degraded propagation in one of several forms; strong signal absorption, brief periods of strong signal enhancement, which is mainly caused by tilts in the ionosphere that allow signals to become focused at your location or very erratic signal behavior in the form of strong and rapid fading, etc., caused by a variety of effects such as multi-pathing, anomalous and rapid variations in absorption, non-great-circle propagation, horizontal or side refraction and/or scatter (skewing) due to changes in electron density and polarization changes. (See definition #7. Propagation Path Skewing).

When the Aurora Oval zones are contracted and latitudinally-thin coinciding with low geomagnetic activity, it is possible for a medium-frequency transmitted signal to propagate through the Aurora Oval zone without being heavily absorbed by skirting underneath it.



26may90
Major flare and geomagnetic storm, propagation never had much of a chance! Return..



record of 01 September, 1990

This record for 01 September, 1990 indicates that not all geomagnetic activity necessarily destroys propagation. This day with Ap=26 had conditions ranging from quiet to major storm yet the openings remain generally good. Geomagnetic storms in fact can be quite local and do not a priori indicate poor communications. Recall that my recordings only probe a small portion of the ionosphere located about halfway between Ft. Collins, Colorado and Houston, Texas.

Supplemental Records

During periods of very low geomagnetic activity, areas of the Aurora Oval zones may only have a latitudinal thickness of approximately 300 miles. But radio signals reflected from the E layer can travel over distances of as much as 300 to 1250 miles at heights below the ionosphere for low take-off angles of between 10 and 25 degrees. When the geometry is just right, the medium-frequency transmitted signal can literally propagate underneath and through the Aurora Oval zones into the polar ionosphere which is less disturbed and from the polar ionosphere back into the middle latitude ionosphere, without ever coming in contact with the highly absorptive Aurora Ionosphere. This type of propagation is not as rare as you might think and it can provide unusually stable polar region path openings to (TA) Transatlantic and (TP) Transpacific regions. But because the Aurora Oval zone expands and contracts constantly, such conditions often do not last very long. (See definition #3. Equatorial Ring Current).

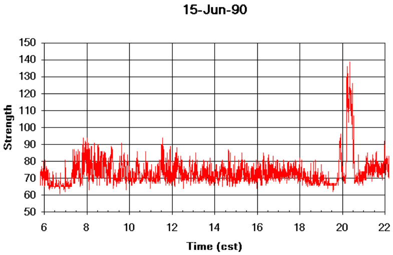
3.) Equatorial Ring Current-

A phenomenon that acts as a repository for precipitated electrons in the vicinity of the magnetic equator. The electrons travel by spiraling around north south magnetic field lines at a frequency called the 'gyro frequency. The end result is lower latitude propagation path medium frequency transmitted RF signal blockage and absorption via the D layer. Absorption is similar to higher latitude Aurora Oval absorption and is inter-related with same.

A reliable gauge for measuring the up to three day lingering post geomagnetic storming medium frequency transmitted RF absorption is the Dst index, measured in nT's. It is an estimated value from Kyoto Japan and is based on a formula. Large negative values after a major geomagnetic storm indicates a high Equatorial Ring Current level. (See definition #2. Aurora Oval Blockage, Absorption And Refraction). Here is a website link to the Kyoto, Japan Dst Index http://swdcwww.kugi.kyoto-u.ac.jp/dst_realtime/presentmonth/index.html and the U.C. Berkeley website link http://sprg.ssl.berkeley.edu/dst_index and a NASA GSFC website link http://sprg.ssl.berkeley.edu/dst_index . (See definition #2. Aurora Oval Blockage, Absorption And Refraction). Another excellent source of a daily Dst figure is at http://www.alan.melia.btinternet.co.uk/latest.htm .

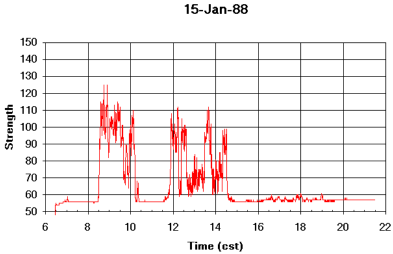


record of 15 June, 1990

Another storm ending on 15 June, 1990 in the summer season has in this record nearly wiped out the opening totally. Ap for the record also a high 47. Similarly, the flare and storm on 26 May, 1990 with an Ap=38 had terrible results for communications.

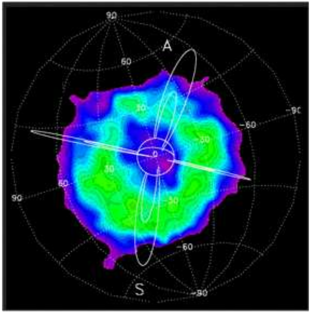
Unsettled to Active Field Response

Solar activity can cause disruptions of the earth's magnetic field leading to choppy or poor openings. The usual cause of these disruptions is the interaction of charged particles expelled from the sun by flares with the earth's ionosphere. Being charged, they carry magnetic field lines from the sun and distort the local earth field lines. The effects are most pronounced when the sun's magnetic poles are reversed with respect to the earth's. Even when sunspot activity seems low particles can still be ejected through coronal holes and disrupt local conditions.



record of 15 January, 1988

This record of 15 January, 1988 was taken on the last day of a major geomagnetic storm. The planetary "Ap" value, (a measure of geomagnetic activity) was a high 45. The openings here are choppy, short lived but still with good signal strengths typical of a winter record.



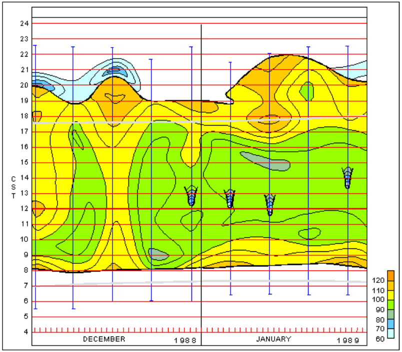
4.) Coronal Mass Ejection (CME)-

A Coronal Mass Ejection is the name given to an ejection of a large amount of matter from the Sun's outer atmosphere or corona. These ejections typically comprise millions of tons of material in the form of charged particles and can be seen because the material reflects sunlight. When one of these ejections is directed towards the Earth (or conversely, directly away from the Earth), it looks like a roughly circular "halo" surrounding the blanked out Sun.

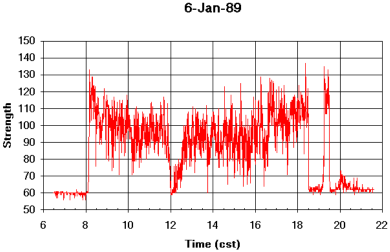
The "Halo CME's" are those CME's which are more likely to impact the Earth than those which are shot out at right angles to the Earth-Sun line. Energetic protons emitted during CME's play a major role in increased day time and night-time D layer absorption of medium frequencies.

Coronal Mass Ejections were once thought to be completely initiated by solar flares. However it is now known that many (CME's) are not associated with Solar Flares but instead with collapsing Solar Filaments. If a (CME) collides with the Earth, it can excite a Geomagnetic Storm if the polarity of the Interplanetary Magnetic Field (IMF) has a negative sign. We must be vigilant in watching for geo-effective (CME's), in order to not be caught by surprise with a seemingly sudden and unexpected Geomagnetic Storm. (See definition #6. Solar Filament). (See definition #11. Geomagnetic/Ionosphere Storm). (See definition #16. Solar Flare).

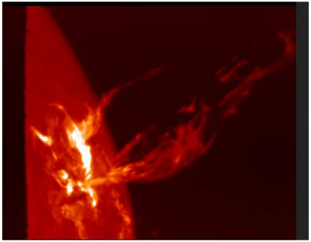
Coronal Mass Ejections are not random meaningless eruptions but instead a process by which the Sun expels complex magnetic signatures enroute to changing its magnetic polarity or said a different way the swapping of the Sun's magnetic poles. Basically the Sun swapped its magnetic polarity at the peak of present solar cycle 23 somewhere between July 2000 and December 2001. The next polarity swap will occur during solar cycle 24 somewhere around 2012.



Map for the winter 88/89 which shows the typical short openings and strong signals. Major flares on 30 Dec, 88, 1802 UT (1202 CST); 06 Jan, 90, 1805 UT (1205 CST); 13 Jan, 89, 1734UT (1134 CST); and 27 Jan, 89, 1917UT (1317 CST). Solar flux during the period was understandably high hovering between 154 and 170 in early December, jumping to 180 to 290 through January 89.



Major flare at 1805UT, (1205 CST). Also note the evening signal dropout and return.

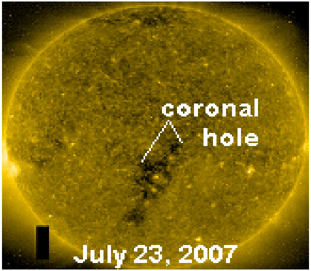


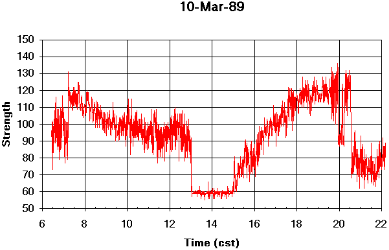
5.) Coronal Hole-

The Corona is not part of the Sun's surface. It is instead part of the Sun's atmosphere, much like Earth's troposphere. Coronal Holes are low density areas associated with open magnetic field lines and are found near the Sun's poles at the bottom of a sunspot cycle and everywhere during a cycle maximum. A Coronal Hole is a dark region where a breakdown in the magnetic field structure in the solar corona has occurred. From these regions stream the high velocity solar wind that is a source of geomagnetic storming on Earth.

Coronal Holes occur most often on the downside of a solar cycle and their absence at the bottom of a solar cycle and at the beginning of the next, allow for the best medium frequency radio propagation conditions. Many think it's the lower solar flux values seen at the bottom of a solar cycle that accounts for improved propagation conditions but it's actually pretty much a lack of Coronal Holes and geomagnetic storming. (See definition #11. Geomagnetic/Ionosphere Storm).

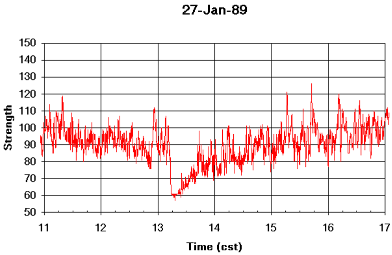
One thing to keep in mind is that the high velocity solar wind stream emanating from a Coronal Hole is a neutral phenomenon with respect to the Bz (magnetic component) of the Interplanetary Magnetic Field (IMF). If the Bz component is negative (southward) prior to arrival of the solar stream, there will exist a tendency to see a larger swing negative after the disturbance arrives. If the Bz component is positive (northward) prior to arrival of the solar stream, there will exist a tendency to see a larger swing positive after the disturbance arrives.





See «http://www.ips.oz.au/background/richard/power_1989.shtmll » for a description of the event and its effects in Quebec. Next: Unsettled to active field response..

Supplemental Records

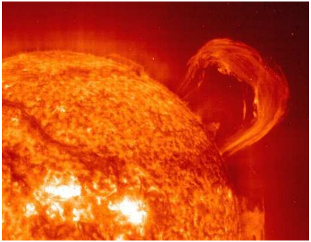


record of 27 January, 1989, detail

The above detail shows more clearly the sudden drop followed be a rise back to the former signal level. This was a pretty typical flare, strong but not truly large. Another example of a typical flare comes from the record of 06 January, 1989. The winter and spring of 1989 was a very active period for flares and I caught them repeatedly on many records as the map for December 89 / January 90 shows. On the 10th of March, 1989 there occurred a truly powerful outburst which blocked radio communications for several hours and the geomagnetic storm that followed three days later was so severe that it knocked out the power grid in Quebec, Canada, and caused wonderful auroral displays as far south as Florida.
record of 10 March, 1989

6.) Solar Filament-

A relatively cool and dense ribbon of gas held together by solar magnetic fields. From Earth they usually appear as relatively dark lines across the face of the Sun. At times the magnetic lines holding the filament open up creating a tremendous eruption similar in size and impact of a Coronal Mass Ejection (CME). (See definition #4. Coronal Mass Ejection). (See definition #11. Geomagnetic/Ionosphere Storm).



7.) Correlation Of Energetic Protons, Solar Flux and Ap & Kp Indices With Medium Frequencies-

I've been observing energetic proton levels, as well as the Ap & Kp indices for 35 years and see a direct correlation between high energetic proton levels above 10 MeV (10+0) and poor propagation on high and at times mid latitude medium frequency paths at day AND night, where as the A & K indices don't as readily correlate. (See paragraph three of definition #2. Aurora Oval Blockage, Absorption And Refraction) and (definition #7. High Latitude Path Skewing) for a further explanation on the lack of correlation of Ap & Kp indices with medium frequency propagation conditions.

High solar flux values are "incorrectly" considered to be detrimental to medium frequency signals both domestic and TA/TP, as more absorption can be present as the transmitted signal makes two trips through the D layer, near sunrise and sunset. However most medium wave frequency RF signals in excess of 3100 miles are propagated via the E valley/F layer ducting and/or Chordal Hop/Pederson Ray propagation mechanism and a high solar flux value ensures a strong E valley/F layer duct mechanism. Actually a solar flux of at least 150 is needed for a consistent E valley/F layer ducting mode.

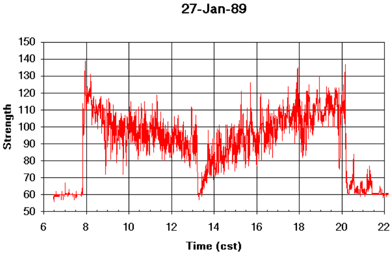
The main reason that medium frequency radio propagation "seems to be better" at the bottom of a sunspot cycle is not so much due to lower solar flux levels BUT due to much less geomagnetic activity.

Keep in mind though that the 10.7 cm (2800 MHz) solar flux index is not a "reliable" gauge of ionization in our atmosphere, as the energy of photons at this frequency is to low on the order of one million times. However most are used to solar flux and sunspot number and it's a hard habit to break. A better indicator is the inter-related background X-ray flux. (See definition #1 paragraphs e & f).

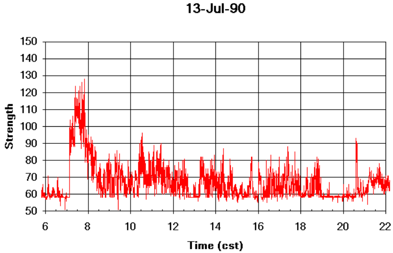
An elevated energetic proton flux level greater then (10+0) creates noticeably increased winter time day and year round night time D layer absorption of medium wave frequencies, especially on high latitude propagation paths but it can also

Flare Response

Flares result from the sudden release of tremendous amounts of energy from the sun's surface. Some eight minutes after a flare bursts on the sun, high energy ultraviolet radiation impacts the earth ionizing all the ionosphere layers in the process. While this might be expected to enhance F layer propagation, the D layer density quickly becomes opaque to the signal causing a sudden fadeout. Depending on the duration of the flare, the fadeout will last from minutes to hours and then as the ions recombine there follows a logarithmic rise back to normal. The following record of 27 January shows a classic flare signature against a clean winter record.



record of 27 January, 1989



Summertime blues, solar flux good at 153, Ap=10, pretty quiet day but with lousy reception.

negatively impact mid latitudes, depending on the intensity of the event.

Elevated energetic proton events too small to be categorized as a Polar Cap Absorption event (PCA) can still impact high and at times mid latitude medium frequency propagation paths in the form of excessive D layer absorption.

((((Note, high latitude medium frequency radio propagation paths can still be disturbed for days and up to weeks, following the end of an official >10 MeV (10+0) proton event.))))

GENERAL GUIDELINES CONCERNING CORRELATION OF PROPAGATION INDICES TO ACTUAL MF PROPAGATION CONDITIONS-

NOTE!!! The propagation indices "interpretations" are my personal intellectual property. Therefore the propagation indices interpretations contained herein is copyrighted © 1988-2013 by Thomas F. Giella, W4HM, all rights reserved. Reproduction of information herein is allowed without permission in advance as long as proper credit is given.

All 13 of the following indices have to occur as described below in order to see the best global medium frequency (MF) radio wave propagation possible.

1.) Dropping geomagnetic field indices numbers are better, Kp of 0 best.

2.) A daily sunspot number under 100, under 70 best.

3.) A daily sunspot number no higher then the 100 for routine stable formation of the E Valley/F Layer ducting mechanism.

4.) Previous 24 hour Ap index under 10, fewer than 7 for several days consecutively are best.

5.) Previous 3 hours Kp index fewer than 3 for mid latitude paths, fewer than 2 for high latitude paths, 0 for several days consecutively is best.

6.) Energetic proton flux levels no greater than 10 MeV (10+0).

7.) Background x-ray flux levels of A0 for several days consecutively.

8.) No current STRATWARM alert.

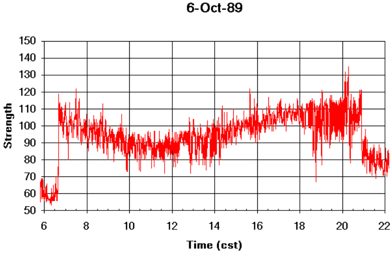
9.) Interplanetary magnetic field (IMF) Bz with a (positive number) sign, indicates a lesser chance of high latitude path aurora absorption/unpredictable refraction or scattering of medium frequency RF signals, when the Kp is above 3.

10.) A -10 or better towards a positive number Dst index during the recovery time after a geomagnetic storm, as related to the equatorial ring current. A positive number is best.

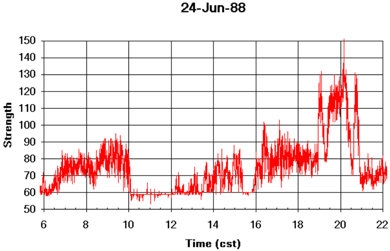
11.) Galactic cosmic rays decrease to -3 units below zero and trending towards zero.

12.) Energetic electrons no greater than 2 MeV (2+0).

13. A solar wind speed of less than 300 km/s for several days consecutively.

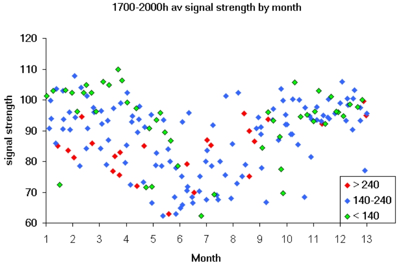


"Ideal" recording with winter response, good opening, midday sag, and long evening period with strong signal reception.



Major flare at 1609UT (1009 CST).

average strength for the midday period 1700 - 2000 UT



The following section shows the signature of a solar flare since finally, that’s what all this is about!

Supplemental:

GENERAL GUIDELINES CONCERNING CORRELATION OF PROPAGATION INDICES TO ACTUAL HF PROPAGATION CONDITIONS-

NOTE!!! The propagation indices "interpretations" are my personal intellectual property. Therefore the propagation indices interpretations contained herein is copyrighted © 1988-2013 by Thomas F. Giella, W4HM, all rights reserved. Reproduction of information herein is allowed without permission in advance as long as proper credit is given.

All 14 of the following indices have to occur as described below in order to see the best global high frequency (HF) radio wave propagation possible.

1.) Dropping geomagnetic field indices numbers are better, Kp of 0 best.

2.) A daily sunspot number of 150 or higher, 200 or higher best.

3.) A daily sunspot number of greater than 100 for routine stable formation of the E Valley/F Layer ducting mechanism.

4.) Previous 24 hour Ap index under 10, fewer than 7 for several days consecutively are best.

5.) Previous 3 hours Kp index fewer than 3 for mid latitude paths, fewer than 2 for high latitude paths, 0 for several days consecutively is best.

6.) Energetic proton flux levels no greater than 10 MeV (10+0).

7.) Background x-ray flux levels greater than B1 for several days consecutively, greater than C1 best.

8.) No current STRATWARM alert.

9.) Interplanetary magnetic field (IMF) Bz with a (positive number) sign, indicates a lesser chance of high latitude path aurora absorption/unpredictable refraction or scattering of medium frequency RF signals, when the Kp is above 3.

10.) A -10 or better towards a positive number Dst index during the recovery time after a geomagnetic storm, as related to the equatorial ring current. A positive number is best.

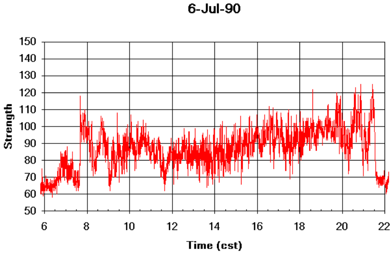
11.) Rising positive T index number. The T Index tracks with the F2 layer critical frequency (foF2) and sunspot number (SSN) and indicates the capability of the F2 layer to refract RF signals.

12.) Galactic cosmic rays decrease to -3 units below zero and trending towards zero.

13.) Energetic electron flux levels no greater than 2 Mev (2+0).

14. A solar wind speed of less than 300 km/s for several days consecutively.

8.) E Valley/F Layer Propagation Ducting Mechanism/Chordal Hop Propagation-

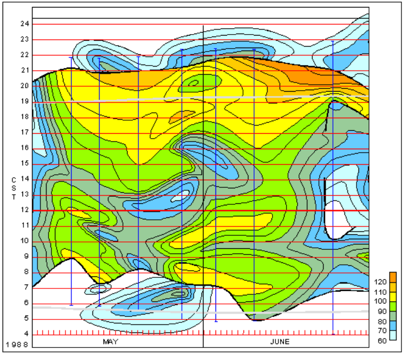


record taken on 06 July, 1990

This chart shows a fairly typical (if there is such a thing) "summer" record taken on 06 July, 1990. The day had strong solar flux at 209, and the geomagnetic field was moderately quiet. Still, the signal was weak most of the day with lots of noise and levels only in the S3 - S5 (80 - 90) range. A week later on 13 July the opening made a brief appearance in the morning and then headed south all day. Good day to go fishing.

I have taken averaged hourly signal strengths for all 200 records and put them on a spreadsheet to make further analyses. The following graph shows the average strength for the midday period 1700 - 2000 UT (10am to 1pm CST) averaged together and plotted by month. That is, all February data regardless of year together, all June and so forth. Although some years may be better overall, you can clearly see the seasonal signature with good autumn to spring signal and poor summer reception.

generally the records are choppy and noisy, fading is a far bigger problem.



period of June and July, 1988

On 24 June of this period there occurred a major flare at 1609UT (1009CST) which closed the window for several hours.

Antenna polarization plays a large role in the success of a long haul DX contact. As a medium frequency RF signal traverses our planets magnetic lines of force in a perpendicular manner on high and mid latitude paths say between W3 land and SM, higher angle horizontally polarized signals are more readily absorbed then lower angle vertically polarized signals. On other paths on the globe opposite results can be found, i.e. horizontally polarized signals suffer less absorption on a propagation path between VK6 and W4.

You would expect a true long path QSO on 160 to be theoretically possible but improbable on most paths during any season. However a G to VK long path might be possible if the E Valley/F layer ducting propagation mechanism or the Chordal Hop propagation mechanism is involved. A 160 meter signal can traverse a daylight path via these propagation modes if the transmitted signal enters/exits at each end of the path at or near sunrise/sunset when the D layer ionization is weak (ionosphere tilting).

There is an upward tilt of ionosphere layers towards the east at sunrise. As a result, signals coming from the west are refracted upward at steeper angles and are therefore heard better on higher angle antennas. The opposite is true at local sunset.

A note though, the E-valley/F layer ducting propagation mechanism does not exist only during gray line periods. Internal Buoyancy/Gravity Waves (IBGW's) are a source of the ducting mechanism and allow for occurrences of ducting along any propagation path in total darkness. Measurement of the timing of arrival of propagated medium frequency RF signals demonstrates the existence of the ducting mechanism, versus conventional numerous E layer land/ocean surface hops.

The majority of the time medium frequency RF signals in excess of approximately 3200 miles propagate via the E Valley/F Layer propagation mechanism or via the Chordal Hop (mostly on HF near local sunrise and sunset) propagation mechanism. Typically the majority of transmit antenna's radiation must be focused between 40-60 deg. to enter the E Valley/F Layer duct. (See definition #23.) The Gray line/Gray line Propagation).

A solar flux of at least 150 is necessary for routine stable formation of the E Valley/F Layer ducting mechanism. Therefore formation of the duct is less prevalent at the bottom of solar cycle and long haul propagation poorer at solar minimum.

You won't see this in any mainstream books on radio wave propagation but the vast majority of the time MF and HF signals travel around the world not by successive hops off of the F/F2 layer and the surface of the earth, whether it be landmasses and/or the ocean, but either between the E and F/F2 layer. This is especially true on long paths.
Well Known Chordal Hop LP Routes Courtesy Of Larry Duncan K4WLS-

Here are some well known Chordal Hop LP routes from the East Coast and Mid-West:
